

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

### Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

### About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

## NOTES FROM CLINICAL LECTURES,

*Delivered during the present Session,  
at Univers. Coll. Hospital,*

BY C. J. B. WILLIAMS, M.D., F.R.S.

Professor of the Practice of Medicine,  
and of Clinical Medicine.

SINCE my last clinical lecture, the patient, Thomas Stocks, has died of phthisis; and I will take the opportunity of commenting on all the cases of phthisis, or complicated with pulmonary tubercles, that have come under our notice among the in-patients since the beginning of the session.

Of 98 [patients who have been, or are, under my care since the beginning of Oct., no fewer than 28 (which is one in three and a half) have presented signs of tubercles in the lungs. You may think this a very large proportion; and I have no doubt that it is much larger than the proportion of patients, generally called phthisical, is found to bear in any hospital. But, remember, I number not only the cases of obvious phthisis, but those of other diseases in which there were distinct signs of pulmonary tubercles to any extent. In fact, of this number, 28, at least 13 were cases either of latent phthisis, or of pulmonary tubercles disguised by other diseases, and which, but for their physical signs, we would not pronounce (perhaps not always even suspect) to be tuberculous at all.

On the other hand, you must take into account the fact, that the common obvious cases of phthisis are not generally admitted into the hospital. On account of the commonly incurable and lingering character of pulmonary consumption, patients suffering from it are not considered proper objects for in-door treatment; for, if such were admitted, there would be no room for the subjects of other diseases, which do admit of cure, or at least of relief in a shorter time.

Considering, therefore, that many cases of  
747.—xxx.

phthisis are excluded from the hospital, it must again strike you that our proportion of tuberculous cases is very high. Yet I am convinced, from extensive observation and much reflection on this subject, that tuberculous disease of the lungs, in some degree or another, in one form or another, prevails among the more seriously sick in London, and in other large towns, in as great a proportion as among our patients. So far as our post-mortem examinations have given the opportunity, you have seen verified the statement which you have often heard me make, that of those in large towns who die of various diseases or accidents, above the age of thirty, more than half exhibit in the lungs more or less of tuberculous disease, or of the traces which it leaves behind. It is thus only we can learn the real amount and importance that tuberculous disease bears in the scale of maladies, by regarding it not only in its more acknowledged forms, and attended by its common symptoms, but by aid of careful physical diagnosis, or of the still more minute search of the scalpel, tracing it in all its degrees and combinations, as a secondary lesion and as a primary affection, as an index of the state of the constitution, as well as in the more decided form of an extensive organic disease.

It is by extensive observations and comparisons of this kind that I have been led to entertain the views with regard to tubercle, and the diseases which it produces, which I have given in my lectures at the College, and of which you will find an outline in various works which have been published in the last fourteen years. A fundamental part of these views is, that tubercle is the *plasma* or material with which textures are nourished or repaired, in a degraded state, which may be either *cacoplastic*, when it forms dense, ill-organized, and non-vascular deposits (as in grey tubercle), or *aplastic*, when it is still further devoid of living organization, as in yellow tubercle.

This view, by regarding tubercle as a deviation in degree rather than in kind from

natural processes, and by associating it with the universally operating function of textural nutrition, explains the frequency and mode of its production in such various constitutions, and under such a variety of circumstances, and I think I may add, guides us to the methods of treatment which have been most sanctioned by the most extensive experience.

I shall group together our cases according to their forms or complications; and as we have not time to give the details of each case, I refer you to the reports for these, and shall make a few general remarks on each group.

*Phthisis, simple, or with mere bronchitis.*

Of this class we have only four cases; for this is the unfortunate class that is generally excluded from the hospital. When they are taken in, it is either on account of some recent exacerbation, or simply *misericordias causæ*.

The case of Thomas Stocks, who was admitted October the 12th, and died February the 22d, is one of common constitutional phthisis, in a young man who had lost several brothers and sisters in the complaint, and himself became a victim of one of its most extensive and rather rapid forms. We have kept him in the hospital as a specimen of the ordinary simple form of this disease. You have had the opportunity of watching its steady progress, with its symptoms of cough, with copious muco-purulent expectoration in opaque flocculent masses, extreme shortness of breath, ever frequent pulse, increasing debility, and pallid emaciation, with occasional profuse night sweats, but with little pain or other severe symptom to ruffle the path to the grave. Physical examination too has shown the nature and progress of the disease in the lungs, by irregular dulness of various parts of the chest, particularly the upper; in the defective vesicular breath-sound, and in the loud whiffing, and cavernous breath-sounds, varied occasionally by cavernous and other rhonchi, and becoming more extensive with the consuming advancement of the disease. This patient bore tonics and full diet well; and I have no doubt that these prolonged his ebbing life; whilst the opiates, in various forms, greatly relieved the cough. On some occasions it was necessary to intermit these measures on account of increased dyspnoea, consequent on diminution of the expectoration: under these circumstances relief was afforded by a blister, and the use of an expectorant, consisting of decoction of senega, with ammonia, squill, and conium.

In the post-mortem examination we found the lungs so extensively consolidated by tuberculous deposits, and those of circum-

scribing inflammation, and so pervaded by cavities of all sizes and degrees, that very little natural vesicular texture was left, and it seemed a marvel how life could have been sustained so long; but you must seek for an explanation in the proportionate reduction of all the organic functions; so that life being reduced altogether to a lower scale was sustained with less and less breath. We found universal adhesions agglutinating not only the pleuræ, but also the heart to the pericardium; and as there appears to be no account of a previous attack of pericarditis, the latter must be referred to an extension of the low, latent inflammation, with which tuberculous disease is so commonly associated.

Edward Lester, æt. 35, formerly intemperate, dated the commencement of his chest complaint to a severe cold five years ago, during which he spit blood. He was admitted Dec. the 17th, in an advanced stage of phthisis, with all its symptoms and signs, and was dismissed unrelieved Jan. the 15th. The plan of diffusing iodine and watery vapour through the room was tried with this patient. It produced an effect which often follows from its use, that of diminishing, for a few hours, the cough and the expectoration, but increasing the dyspnoea; and when the cough did return, it was unusually violent, the expectoration more viscid, and tinged with blood.

Richard Ferral, ætat. 40, admitted November 26, a stout man, caught cold from wet feet six months ago, and has coughed ever since, with frothy expectoration occasionally tinged with blood: has gradually lost flesh and strength. Signs of partial consolidation and small cavities under both clavicles; dulness and subcrepitant rhonchus in the posterior part of both lungs. Pulse 80, weak. He was treated by blisters, followed by the turpentine and acetic acid liniment, with nitro-muriatic acid and ben-bane internally. He was much relieved, but on December 10, the expectoration becoming more scanty and difficult, with an increase of dyspnoea, an alkaline expectorant of senega, squill, carb. potass, and conium, was substituted for the acid mixture with much advantage, and he was dismissed December 17, much stronger and with little cough, the breath sound being clearer and free from rhonchus in the lower parts of the lung, and the dulness under the clavicles diminished but not removed.

James Currey, of intemperate habits, admitted February 15, with chronic phthisis, much aggravated by a recent excess at a wake, had, in addition to signs of consolidation in the upper part of both lungs, impaired stroke sound and breath sound, with subcrepitant rhonchus in the lower part of both

lungs. The latter signs, depending on congestion and bronchitis, were removed by repeated blistering, and a mixture containing  $\frac{1}{4}$  grain doses of tartar emetic with conium. The dulness under the clavicles, especially the right, remained on the 25th of February, when he was dismissed, much relieved of the cough and shortness of breath.

The last two cases illustrate very well how much relief the rest and protection of a hospital, as well as the treatment, often afford to the exacerbations which ruffle and hasten the course of the chronic forms of phthisis. These exacerbations generally arise from congestion or inflammation of the air-tubes, or of the pulmonary texture; and if treated in time, are signally relieved by local depletion, blistering, or other modes of counter-irritation, combined in the more inflammatory cases with antimonials internally, and in the more congestive and asthenic, with acid mixtures, or alkaline expectorants, according to the state of the expectoration. So great is the relief in many cases, that the patients often fancy themselves quite cured; and no doubt most of the cases of reputed cures of consumption are of this kind. But physical examination shows that the tuberculous disease, although quiescent, is not removed; and if it do not advance of itself, it only waits for a fresh exposure to cold or undue exertion, or irregularity of diet, or other cause of disorder, to bring back its inflammatory complications, each return of which adds to the mischief, and reduces the strength, until the consumptive disease becomes continued and wholly irremediable. But although a careful and continued observation of these chronic cases shows the error of supposing them to be cured, it shows how much they may be relieved, and life prolonged, both by studying to avoid the causes of the aggravations of the disease, and by treating these aggravations promptly when they do occur.

*Phthisis with pneumonia:—Two cases.*

Jerry Leonard, æt. 43, admitted Nov. 2, of stout make, formerly intemperate. Mother died of a "cough:" 18 out of 19 of his brothers and sisters have died before they were 18 years of age. Five years ago he was laid up for many weeks with pleurisy. Has had a cough for four months, and a fortnight ago this became much worse after his working in a very damp place. Has lost flesh, strength, and appetite. Breath very short, with pain in left chest. Expectoration viscid, mucopurulent, streaked, and partially tinged with blood. Pulse 90, weak but sharp. Rigors and occasional sweats. Dulness over whole left chest, with defective breath sound, and short crepitation in lower and middle parts. Cavernal respiration, without pectoriloquy, under left

clavicle. Pectoriloquy and subcrepitation below right clavicle.

This patient was treated first by blisters and antimonials until the pain was removed and the breathing better. Afterwards, the cough being very violent, and the expectoration difficult, extract of belladonna, and tincture of squilla, and liq. potassæ, gave much relief for a time. The sweats and debility much increasing, sulphuric acid and the sulphate of zinc were substituted for the alkali. This change seemed beneficial at first, but in a few days the expectoration becoming more viscid and rusty, and the breathing more difficult, the alkali was again used with fresh temporary benefit; and decoction of bark was afterwards added. The dulness in the left side was diminished in the middle and lower part, and some breath sound restored; but the disease in the upper regions of the chest had increased, and so had his weakness and emaciation. He left the hospital Jan. 29th.

The other case is that of John Penelli, which I shall pass over, because I have noticed it in a former lecture.

The supervention of extensive pneumonia in a tuberculous subject, constitutes a most serious complication, which, if not treated early, rarely fails to greatly accelerate the fatal termination of the disease. Many cases of acute phthisis, or galloping consumption, are those aggravated by pneumonia. The lungs are then found more or less consolidated by soft deposit, like in hepatization, but the deposit is more grey or stone-coloured, mottled with older tuberculous deposits, and often spotted with incipient excavations or tuberculous softening. The lymph effused is all cacoplastic, susceptible of neither absorption nor organization: it therefore becomes a serious additional cause of pulmonary obstruction and destruction.

Yet these intercurrent inflammations, if treated early, before effusion of lymph takes place, are often quite tractable, yielding to even moderate antiphlogistic measures, such as local depletion and blistering, and especially tartar emetic internally. The mischief is often done before this treatment is applied, because the symptoms of these inflammations are very obscure, and are ascribed to the tuberculous disease, or sometimes to mere weakness. But you should watch every exacerbation in a consumptive patient; and if you find crepitation and increasing dulness in any part of the chest, or rustiness and viscosity of the sputa, it will be prudent to use some of the moderate antiphlogistic means which I have mentioned, proportioning them to the previous strength of the patient. After these signs have been removed, the usual tonic plan may be again pursued.

*Phthisis, with chronic laryngitis.—**Two cases.*

The case of Sarah Hunt was scarcely within the period of the session, having been discharged, apparently convalescent, Sept. 25th. But I notice it in order to point out how tuberculous disease of the lungs is apt to be combined with chronic laryngeal affections. The attack began six weeks before admission (Aug. 26th) with loss of voice, followed by a croupy cough, difficult breathing and deglutition. These symptoms were much relieved by leeching and blistering the throat, ordered by Dr. Taylor in my absence. On my return, I found her without voice, and still complaining of some cough and dyspnoea, and on examining the chest, detected dulness and defective motion of the outer upper part of left chest, with slight mucous rhonchus. The breath-sounds were masked by a rough laryngeal rhonchus. I ordered her sarsaparilla with iodide of potassium internally, and the tincture of acetic acid liniment. In a week, the patient lost the cough and shortness of breath, but she had not recovered her voice, and the dulness remained.

The other case, Cornelius Sullivan, admitted Jan. 5th, was a more obvious case of phthisis, little advanced, with severe chronic laryngitis. He was first put under the antimonial treatment, with blistering, to relieve an aggravation from recent bronchitis; and afterwards the same remedies were used as in the last case, with the addition of the daily application to the throat of a strong solution of the nitrate of silver, after the method of Trousseau and Belloc. He was discharged Jan. 24th, with very little cough, and his voice restored, although still hoarse.

The more I see of chronic laryngeal cases, the more I become convinced that they are combined either with pulmonary tubercles, or with a disposition to their formation.

*Phthisis, with disease of the heart.—**Three cases.*

I have before commented on the case of John Hudson, who was admitted Nov. 9th, for vertigo and palpitation, connected with dyspepsia and hypertrophy of the left ventricle. As he became relieved from these symptoms, we found that he had had a cough for many months; and we found signs of limited consolidation of one lung. The disease was quite chronic, and unfit for hospital treatment.

Edward Pope was admitted November 25, in an advanced stage of phthisis, under the symptoms of which he had been suffering for three years; and he died January 29. We could not obtain an examination of the body, on account of the objections of the relations. In addition to the ordinary

symptoms of advanced phthisis, he suffered much from occasional attacks of spasmodic dyspnoea and palpitation, which were sometimes relieved by extracts of stramonium and belladonna, or ether and tincture of lobelia. In the fits of palpitation, the pulse at the wrist was innumerable, but by listening to the heart could be easily counted as many as 216 in the minute. Once, whilst we were examining him, the pulsations suddenly slackened down to 100. This is often observed with palpitation. There were signs of enlargement of the heart; the patient had formerly suffered from rheumatic fever.

Elizabeth Freethy also had disease of the heart, originating in repeated attack of rheumatism, and her late symptoms have compelled me to count her among the tuberculous subjects. The heart affection is dilated hypertrophy, causing extended dulness and impulse, and a slight disease of the aortic orifice, indicated by a slight fling murmur at midsternum, not heard below the left breast. I shall have to notice this case under another head.

Disease of the heart is not a common complication with the worst forms of phthisis; in fact, experience has led me to consider hypertrophy of the heart as a favourable circumstance in a case of phthisis; persons having this combination generally exhibiting more power to resist the progress of the tuberculous disease, which consequently becomes circumscribed and chronic. In the most rapid cases of consumption, we often find the heart smaller than usual; and in these the weak pulse and feeble circulation corresponded with their speedy sinking.

The complication with hypertrophy often, however, carries with it an increased tendency to pulmonary congestion and hæmorrhage, and may require more of local depletion and sedative treatment than is expedient in other cases of limited tubercle of the lungs.

*Phthisis, with Rheumatism, Sciatica, &c.—Six Cases.*

I have just adverted to the case of Freethy, who has been twice under my care for an obstinate form of rheumatism, from former attacks of which the heart is permanently damaged. This constant disposition to the recurrence of rheumatism shows something to be very wrong in the constitution. Probably, as Dr. Prout supposes, the chief fault is in the function of secondary assimilation, which is imperfectly performed, and leads to the undue formation of lactic acid or some analogous morbid matter, which is the immediate cause of the rheumatic pains and inflammation. The same cause in time may injure the nutritive material of the blood, and lead to its deposit in a degraded or cacoplastic state; and thus, according to my view, may be formed. The

first symptoms of pulmonary tubercle in the case of Freethy appeared during her stay in the hospital after an attack of feverish sore-throat and catarrh with hepatic congestion. She spat a bloody fluid, which was at first supposed to proceed from the throat; but as the spitting continued, and was accompanied with more cough and pain in the chest, this region was carefully examined; and we found general slight dulness on the right side, with a breath-sound defective in loudness and duration. The disease proceeded in spite of general and local depletions, various counter-irritants, and other remedies; and a month after (February 8), it is reported that the dulness had become more marked, the breath and voice-sound had become tubular under the right clavicle, and slight spitting of blood still continued. On Feb. 9, the catamenia, which had been absent for two periods, appeared; and the chest symptoms were diminished, but not removed. She was then able to bear cascarrilla with nitric acid, which improved her strength, and she was discharged February 21. I have no doubt that ere long the phthisical disease will run its course in this patient, for the constitution is much impaired, and she is continually suffering from various disorders.

In the five other cases, the tuberculous disease of the lungs was more advanced, but limited, and therefore chronic.

James Padger, æt. 62 (admitted September 22, discharged relieved, October 15), suffered from lumbago, and recent bronchitis, of which he was soon relieved; but there was dulness and cavernous breath and voice-sounds under one or both clavicles, with emphysema of the lower lobes of the lungs; a common combination in chronic phthisia.

Edward Robinson (admitted December 18, discharged January 5), came in for chronic rheumatism in the legs, which soon yielded to treatment with iodide of potassium. But he likewise had a long-standing cough, and there were dulness, and cavernous breath and voice-sounds, under the right clavicle, with emphysematous resonance on percussion in the lower region of the chest, down almost to the margin of the ribs.

John Ryan (admitted February 15, discharged February 23), was admitted for rheumatic gout, affecting the ankles and wrists, and other small joints, particularly the right wrist and hand, which was much swollen, and very red and tender. The gouty affection subsided entirely in a few days, under the use of colchicum. But we found signs of a cavern, with partial consolidation at the apex of the right lung; and he stated that he had long suffered from cough, and had lately become very thin. The cough rather increased when the gouty swelling subsided.

Ann Mitchell (admitted January 10,

discharged February 8), was affected with a large and very painful swelling of the right knee, with effusion chiefly in the bursæ. She had also the symptoms of phthisis, with signs of cavities at the apex of both lungs. The inflammation of the knee was cured by leeches, followed by an iodine liniment, with the internal use of iodide of potassium. Her chest symptoms were relieved by blistering and rubefacients, and her strength improved with the use of the iodide of iron.

John Herring, admitted February 26, is still (March 3,) in the hospital, with severe sciatica and signs of tubercles of both lungs, with recent catarrh. He has been treated with colchicum and antimonials, with blistering to the chest, and cupping and a liniment for the hip, and is much relieved.

This number of cases of combined tuberculous and rheumatic or allied affections, seems to point out some real connection between the two diseases. Last summer, some of you may remember that we had several cases of pulmonary tubercle combined with granular disease of the kidney, the frequent connection of which with rheumatism is well known. It is very possible that the pulmonary disease may, in some of these cases, arise from the cachexia connected with imperfect excretion of urine; but I believe the cause of this imperfect excretion, the granular degeneration of the kidney, to be in itself allied to tubercle and analogous caco-plastic products.

## ILLUSTRATIONS

OF THE

### **PATHOLOGY, DIAGNOSIS, & TREATMENT OF OPHTHALMIC AFFECTIONS.**

By EDW. HOCKEN, M.D. M.R.C.S.L. &c.

[Continued from p. 833 of last vol.]

*Definition of granular conjunctiva: forms of the complaint; the symptoms, causes, pathology, and treatment.*

GRANULAR conjunctiva might, with more propriety, be spoken of as *granular inflammation of the conjunctiva*, inasmuch as the condition of the membrane is always to be considered but a part and portion of severe and prolonged inflammation of that tunic, and as never existing distinct from that process. If their inseparable existence be but clearly understood, it will lead to a right comprehension of the pathology of the affection, and scientific plans of treatment. The term "granular" is applicable, from the clearness

with which it conveys to the mind an idea of the appearance of the conjunctiva—a roughened, irregular surface, from the presence of minute elevations or granules; not implying any relationship to the process of granulation in ulcers, from which it differs in every point of view, but simply referring to the obvious characters I have mentioned.

*Definition.*—Hence my definition of granular inflammation is the following:—A severe and prolonged inflammation of the palpebral portion of the conjunctiva, of either active or passive characters, attended by a gradually augmenting and extending papillary roughness or inequality of surface; being of a bright scarlet colour; the granular elevations small, firm, and highly vascular, in active cases, and attended with great intolerance of light, lachrymation, and pain, in advanced stages. In the passive forms, the granulations are large, soft, and dark coloured; there is a secretion of watery mucus, and little pain or irritation is experienced.

I have selected extremes to illustrate my meaning, inasmuch as here, as in all other cases, the contrast must be made in them, the intervening chasm being filled up, in nature, by every intermediate grade. No arbitrary limitations exist in nature, but all is indivisible and connected: there are no abrupt terminations and commencements between this or that law, this or that disease, or the varieties of some one affection; they pass into one another gradually and imperceptibly, and only present a striking contrast in their extremes. We shall not be surprised, therefore, at meeting with cases in which distinctive features, either active or passive, do not exist, and some where the condition is exceedingly mild and slight.

What I understand by active and passive must be explained before I proceed: it involves no theory whatever of the pathology of inflammation. I mean to assert that inflammation may assume either an active or a passive form in any organ, from either constitutional or local causes, or from the specific nature of the exciting agent, being distinguished from each other by constitutional and local symptoms. In the active form there is bright scarlet vascularity, tension, pain, heat, actively

disturbed functions, and pulsation; in the passive dark purple, or livid discoloration, distension of vessels without pulsation, considerable swelling and relaxation; rarely tension, rarely much heat or pain. The constitutional symptoms in the first case are those of synocha, or inflammatory fever; in the second, either depression and derangement of the general health without fever, or a type of fever below the standard of inflammatory, with every intermediate grade, to complete prostration of strength and typhus. It will be obvious that, in this sense, the terms active and passive denote only the *character* of the inflammation, and hence have no reference whatever to its *duration*. I restrict the terms acute and chronic to the *duration* of the disease, and in like manner, as in the former instance, mean to denote no *character* it may possess; for however slow an inflammation may be, it may still be active in its characters, or however rapid, it may still be a passive affection. If all practitioners understood these differences, and used the terms in the foregoing sense, as they should do, no confusion could result, but rather the reverse. Mr. Lawrence's remarks\* on the varieties of inflammation, at the beginning of his work on the "Diseases of the Eye," prove how much a definite meaning attached to these terms is required, since that justly-celebrated surgeon evidently labours under a misapprehension of their true signification when he says, "We read and hear of active, passive, or atonic, of sthenic and asthenic inflammations. Believing inflammation to be increased activity or exertion of the capillaries, I consider the expressions passive, atonic, and asthenic inflammation, as applied to the state of the inflamed part, to be contradictory in terms." Speaking of acute and chronic, the same gentleman has previously remarked (82), "Severity of symptoms and rapidity of progress characterise the former; the opposite attributes of mildness and slowness belong to the latter"; whilst it will be obvious to every one who has faithfully observed nature, that mere duration has nothing to do with the character of the complaint†.

\* Treatise on Diseases of the Eye, 2d ed. p. 83.

† Instead of contending about the presence or absence of increased action, or of weakness in

The forms under which we observe granular inflammation of the conjunctiva correspond with these obvious differences in the types of inflammation generally; but inasmuch as the change, constituting the true form of the disease, requires time for its formation, so in like manner is its progress slow, and its removal a work of time, however judiciously treatment may be timed and adapted. Bearing these facts in mind, it will be obvious that acute and chronic bear but a relative meaning in the present case; the disease is always chronic, but the progress and effects of some cases are much more rapid than others, and hence bear to each other the relative relation of acute and chronic. The grand distinction is between active and passive forms, which differ most materially both in their local and constitutional symptoms, and the treatment which relieves and cures them. The more active cases generally coincide with the more acute, whilst the passive are generally the most chronic. I shall consider them in this relation in my following remarks.

*Symptoms.*—In the active forms of the affection, after some severe inflammation of the palpebral conjunctiva has continued for some time, the severity of the symptoms having been subdued by treatment, an obstinate and intractable chronic form of the same disease remaining, whether the primary affection of the conjunctiva has been induced by the repeated and unscientific introduction of highly irritating or caustic substances between the lids, or Egyptian, or some other form of purulent ophthalmia, a severe sense of roughness and rubbing on the ball of the eye is complained of on any of its motions, the eye waters, its vessels fill, and a severe sense of distress and pain is experienced, rendering the eyes almost useless: this is what the patient

the capillaries, it would be much more to the purpose if we considered the actual combination of morbid phenomena which constitutes inflammatory orgasm. Lesions of innervation and circulation are always combined, and the consequences are lesions of nutrition, whether the primary aberration from the natural condition of nervous state be from the condition of the blood, or originate in causes acting on the nervous system, and secondarily affecting the blood-vessels and blood.

The characters of an inflammation, when of sufficient extent, determine the phenomena of the constitutional disturbance; still, very acute, if not active inflammations, may progress during great prostration, or a typhoid condition of the system.

calls weakness of the eyes. If, in this stage, we invert the lids, we find the changes of granulation to have commenced in that portion of the conjunctiva which is reflected from the globe to the lids, at the angle of its reflection, commencing in the upper lid, and always progressing more rapidly, and with more severity, there, than in the similar situation of the lower one. The granulations are small, more or less conical, firm, very vascular, and of a bright scarlet colour; the conjunctiva oculi, opposed to these, vascular and scarlet; the lids swollen and vascular; there is intolerance of light, and lachrymation.

As the disease proceeds, the symptoms increase in severity, and constitutional ones become superadded. The irregular prominences of the conjunctiva extend on the lids, advancing upon the palpebral surface towards the edges of the lids, but never in the contrary direction, the whole surface becoming eventually crowded with small, firm prominences, more or less conical; many of them, however, very rough and irregular, and some larger than others. These are, of course, (in the natural condition of the lid, presenting a concave surface towards the globe) much crowded, and in close apposition, but on inverting the lid they are separated from one another, and their shapes are more clearly discernible. Whilst the disease has proceeded so as to cover the inner surface of the upper eyelid completely, it generally happens that the lower one is not more than half covered, and by no means so thickly as the upper: a fact which holds good in every form of the complaint. But the progress and completion of these changes in the conjunctiva are not only attended with the mere local symptoms of inflammation and change of structure, but, in addition, those which result from the substitution of a beautifully smooth and soft membrane, gliding over the cornea and conjunctiva oculi, by a rough, inflamed, and thickened membrane. We may thus understand how changes in appearance and function of the conjunctiva oculi, and the transparent continuity of tissue over the cornea, are invariable consequences and attendants of this disease, giving rise to many of the most formidable and painful symptoms, those chiefly noticed by the pa-

tient, and almost characteristic. The perpetual irritation (morbid disturbance) of these parts, leads to great distension of their vessels, and chronic inflammation of their structure; it becomes thickened, highly sensitive, and very vascular; the anterior corneal layer becomes slightly opaque: a few large scarlet trunks with several small diverging branches ramify in its structure: these increase in number in proportion to the activity of the affection, with a proportionate increase in the thickening and opacity of the tissue, till at length, in an advanced stage, it resembles a scarlet cloth, immediately investing the cornea, and hence termed *pannus*.

During the progress of these affections the following symptoms are present: great intolerance of light, so that the patient is quite unable to open the eye in a brilliantly lighted apartment, and spasmodic closure of the lid by the *orbicularis palpebrarum*, powerfully impeding an examination of the organ; profuse lachrymation from any stimulus, and under the same circumstances as previously mentioned; a gummy mucous secretion, which glues the lids together during the night, and which may be seen covering the granulations themselves.

The patient complains of very severe burning pain in the eyes, with the sensation of sand and roughness; weight over the brows, and frequently general headache, and, from the opacity, intolerance of light, and blephorospasmus, almost complete loss of use of the organs. A chronic febrile condition of the constitution accompanies the more active cases, denoted by a hard pulse, impaired digestion, dry skin, and nocturnal chills followed by heat and thirst. I have seen heat of skin and thirst habitually present.

*Passive type.*—In the passive forms of the complaint, the symptoms are much less severe, and more slow in their effects. It commences and progresses in the same way, and in the same manner, as I have already explained; but the irregularities of surface are much larger, much softer, smooth, but irregular in shape, of a dark or sometimes very pale livid colour, and bathed in a profuse watery mucous secretion. The effects of such mechanical irritants on the surface of the globe is much less severe than in

the former instance; the conjunctiva becomes eventually thickened and loaded with dark-coloured vessels, and the front of the cornea irregular and semi-opaque; but there is comparatively little pain, no lachrymation, little, if any, intolerance of light or spasmodic closure of the lids. In many of these cases, the whole structure of the lids is œdematous, of a dark colour, and loaded with vessels.

In all these patients the general health is greatly deranged: there may be fever of a hectic form present, or a simply deranged and depressed constitution. We find the tongue loaded, the breath offensive, the digestion disturbed, the bowels irregular, the skin dry and harsh, perspirations partial and offensive, the urine unnatural, with other similar phenomena. In some cases, the signs of anæmia are present, such as pallor of the countenance, lips, lining of the mouth, and general surface, jerking pulse, &c. &c., with many of the other indications of impaired health I have mentioned.

I have never seen ulceration of the cornea, sloughing, or the formation of staphyloma, produced in any form of the complaint, but an alteration in the condition of the membrane and tarsal cartilage may remain after the cure of the other symptoms, occasioning entropion, which may require subsequent operative treatment. The duration is very uncertain, but in general it is a disease of years or months rather than weeks.

*Causes.*—One of my main objects in communicating this paper at this time, is to dwell somewhat on an occasional cause of this most afflicting malady, and to warn others from the too indiscriminate employment of highly irritating or caustic applications to the conjunctiva. The most fruitful source undoubtedly is some variety or other of purulent ophthalmia, but any cause capable of producing and maintaining for some time a highly inflamed condition of this membrane, may originate the disease. I have watched five or six cases within the last two or three years, which have originated solely in the unscientific, indiscriminate, injudicious, and repeated use of the nitrate of silver, either as a saturated solution, or in substance. They have commenced with some trifling conjunctival affection—a little pain or roughness,

which the patients disregarded until they accidentally passed some Eye Infirmary, or called on some medical attendant of the family in which they were servants; but in all the cases I have alluded to they each and all of them positively denied having suffered from anything more than slight pricking, redness, and feeling of sand in the eye, until they had become the victims of practice—which they themselves termed “hot drops,” and which, when placed between the lids, caused them most dreadful suffering, generally lasting for some hours, after each application. A few condensed notes of two or three of these cases may prove that I am not in the slightest degree exaggerating their truth.

*Active acute granular inflammation of the conjunctiva, occasioned by the indiscriminate employment of the nitrate of silver.*

Mary Gibson, æt. 45, a full, powerful, healthy-looking woman, was admitted under the care of Mr. Lawrence, in St. Bartholomew's Hospital, in the month of January, 1841. She stated, that she had always been of healthy and active habits, and had rarely suffered from any previous indisposition, being quite well until the December of 1839. In the early part of this month she found her eyes rather weak, and complained of something under the lids; but altogether it was so very trifling that she took little notice about it. In the course of the month, finding that the eyes remained “weak,” she applied at an Eye Infirmary, and had something put into her eyes which occasioned the most violent burning pain, lasting for two or three hours, and attended with profuse lachrymation and spasmodic closure of the lids. Her eyes now became so bad that she was obliged to attend frequently, and at each attendance the burning drops were again introduced; invariably being followed by the paroxysm of agony, lasting for two or even three hours. About the end of the month, her eyes were so intolerant of light, watered so profusely, and pained her so much, that she was, to all intents and purposes, blind; and has continued nearly in the same condition ever since, being sometimes better and sometimes worse. Finding that she was invariably worse after every attendance at the Eye In-

firmary, she discontinued to attend; but not before she found that every motion of the eyeball under the lid produced so severe a sense of sand under the lid that it was almost unbearable. In this truly pitiable condition, she applied to a Dispensary, where, after undergoing various treatment, and finding she received no benefit, she continued a patient some time, but eventually forsook this also. She then became a patient of a private practitioner, but having exhausted all her means, she gladly embraced the opportunity of becoming an in-patient at St. Bartholomew's Hospital, under Mr. Lawrence, in Jan. 1841, being in no better condition than she was a year previously.

On her admission we found the lids greatly swollen and vascular; the conjunctiva oculi and front of the cornea thickened, opaque, and of a light scarlet colour; the conjunctiva of both lids crowded with small, firm, highly vascular irregularities; the lids were firmly and spasmodically closed, and very profuse lachrymation was excited on every attempt to examine the organs. She complained of very severe burning pain in the organs, and sense of roughness, weight, and oppression, over the brows, and frequent headache. She had nocturnal fever, dry skin, loaded tongue, disturbed digestion, and general feeling of illness. Mr. Lawrence freely scarified the vascular lids, which bled profusely; leeches were liberally applied around the organs, and an antiphlogistic regimen was adopted. These measures were had frequent recourse to during the nine or ten months she remained in the hospital, and almost invariably with temporary relief; but during that period she several times got much better for a few weeks or days, and then as suddenly became again worse. Several local applications were used during this period. The liquor plumbi seemed to give relief, and shortly afterwards was manifestly injurious. Dilute vinum opii was alternated with solutions of alum, and seemed beneficial when first employed; but no one remedy could be depended on for any length of time. At one period the condition of the lids, and other symptoms, improved so much, that there was every prospect of her recovery; but she again relapsed, and it was not without much difficulty that

the affection again took a favourable turn. Continuing to improve in the autumn of 1841, she was discharged during a favourable period much benefited. How long it was to continue as a permanency was doubtful.

I will now allude to a case of the passive type originating from the same cause.

*Passive granular inflammation of the conjunctiva, connected with feeble general powers and anæmia, brought on by the local application of the nitrate of silver.*

Charles Pendrill, æt. 50, a pale cachectic-looking man, was admitted into St. Bartholomew's, under the care of Mr. Lawrence, in October, 1840. The account he gave of himself was, that he was a gentleman's servant, in the capacity of porter; was in very good health, but that having to open the gates one cold wet night, he caught a slight "cold" in his eye. By his master's orders he applied at an eye infirmary, in which that gentleman was a governor, and where, to use the patient's words, "hot drops were put into his eyes until he lost his sight." He stated that the invariable effect of these "hot drops" was to occasion him severe burning pain in the organ, lasting for two or three hours. In a comparatively short period his eyes became so bad, that he was quite unfitted for any employment; and as they continued to get worse and worse every time he attended, he called at the private residence of the surgeon, who looked at his eyes, said they were very bad, and that he would "touch them up for him;" accordingly they were well "touched up" with nitrate of silver in substance, which greatly increased his former symptoms. The left organ was first affected, speedily followed by the right. Besides the local application of a saturated solution of the nitrate of silver to the organs, tartar emetic was administered internally.

On his admission he enjoyed no useful degree of vision: his lids were crowded with soft, flabby granulations, which secreted a watery mucus; his conjunctivæ oculi thickened, and traversed by dark-coloured vessels; the fronts of the corneæ looked uneven, were dull and opaque, and somewhat vascular; his look was pale and cachectic, and his secretions and excretions were

greatly deranged. His lids were scarified, and astringents were judiciously alternated in solution to the conjunctiva. He was greatly benefited by hospital regimen, and these curative proceedings in some months time, but subject to relapses from very slight causes. Once or twice he was readmitted, and again discharged; the last time in the summer of 1841, when, although his eyes were better, he presented more definite symptoms of anæmia, viz. general pallor, lips and lining of mouth blanched, pulse feeble and jerking. Mr. Lawrence, by my advice, gave iron internally with the most beneficial effects; he rapidly improved in all respects, and was shortly afterwards discharged cured.

*Pathology.*—I shall dwell but little on the intimate nature of the disease: it is essentially inflammatory, has an inflammatory origin, and is caused by the same means which relieve that morbid process and its consequences. Of course it has not the remotest connexion with the granulations of ulcers, for such never spring from a sound surface, nor does it ever depend on enlargement of the meibomian follicles, since, as I have already mentioned, it always commences in, and spreads from, the reflection of the conjunctiva to the lids, where these follicles are absent. There appears to me to be more truth in the statement of its dependence on enlargement of the conjunctival papillæ; partly from the engorgement of vessels, and partly from the deposition of lymph interstitially; and hence, from such a belief, my views on treatment will not appear inconsistent.

*Treatment.*—There are many men who take a very partial and local view of disease, and are very fond of an exclusively local treatment; I cannot connect myself with these, although a judicious employment of local remedies, when combined with their constitutional use, are, in my opinion, far preferable to either separately. In the active forms of this complaint, a suitably active treatment should be pursued, in accordance with the general powers and peculiarities; cupping from the back of the neck, and the application of leeches around the organs, should be employed with the activity and frequency which the case may suggest. Again, the bleeding may be performed locally, by dividing the ves-

sels concerned, most freely scarifying the conjunctiva of the lids in all directions, and shaving off the granulations level with the surface; the lid should be fully inverted, whilst this is performed with a lancet. And here let me state, that the mere shaving off of the inequalities by no means insures a cure; for as long as the inflammation, on which the disease depends, remains unsubdued, the granulations are reproduced. If the operation be performed skilfully, it leaves no inequality of surface, by occasioning depressions, after the disease is cured.

The treatment which I should recommend, in conjunction with these measures, has never been proposed, or used by any one else, as far as I am aware, and yet it appears to me to recommend itself as obviously in this as in any other inflammation connected with the deposition and organization of lymph; I mean the moderate and constitutional action of mercury, quietly introduced into the system until it slightly affects the gums, &c., and then continued in sufficient quantity to maintain its influence.

In passive types, scarification of the diseased membrane is generally useful, but its employment must be determined by its effects.

Astringent applications to the conjunctiva are valuable remedial measures, but they require adaptation to render them useful. A very dilute solution of the plumb. acet., ij. grs. to the ʒj. of aqua rosæ, is best suited to the active acute cases, and the undiluted liq. plumbi to the more passive; managing the intermediate forms according to their character. We find that these remedies, although at first beneficial, frequently lose their effect from long use, and hence require to be alternated, with some degree of tact, with other astringents, as alum, vinum opii., cup. sulph. &c. In some of the very mild cases, nothing more is required than to invert the lids, and to rub the granulations with the sulph. cupri, keeping the lid inverted for some minutes after its use, and repeating the application at intervals.

In all the forms of this complaint, we must bear in mind that the condition of the constitution must be attended to, and its derangements treated appropriately, according whether it be above or below par, deranged and de-

pressed, or its condition disturbed by any morbid poison, paying especial attention to the secretions and excretions.

15, Southampton-street, Covent-garden.

## CASE OF VIOLENT HYSTERIA IN A MAN.

By ALFRED SMEE, F.R.S.,

Surgeon to the General Dispensary, Aldersgate Street; Surgeon to the Bank of England, &c.

(For the London Medical Gazette.)

ON last Christmas-day twelvemonth, I was suddenly aroused from the merriment peculiar to the season, by being informed that one of the Bank porters was in a violent fit. On repairing to the spot, I found a man lying perfectly insensible, surrounded by nearly twenty persons, from whom I could only learn that he had suddenly fallen into that state; and these appeared to be certain that he had not been drinking to excess. What, then, was the cause of the insensibility? was it from poisoning? was it from apoplexy? was it from epilepsy? At the time I first saw him his utter stupor might have led to the supposition of the former; yet his age, twenty-six, was unfavourable to that idea. He threw his head about, groaning a little, but his circulation was not in the least disturbed. Not feeling satisfied as to the nature of his malady, I determined to wait, in spite of the earnest wishes of all surrounding him to do something, or in fact anything, in order that a little time might be allowed for the disorder more fully to manifest itself. To have bled him at that moment, would have delighted all present, for the vulgar prejudice of bleeding, in every case of insensibility, no matter what the cause, is so great, that it is difficult to withstand the manifestation of public opinion which always takes place upon its non-adoption.

After a delay of about three-quarters of an hour, finding he remained in the same absolute stupor, I determined to abstract a very small quantity of blood, carefully feeling my way; but whilst waiting for the tape to effect that object, he raised himself, and laughed in that most violent convulsive manner peculiar to hysteria patients. It was enough: I again felt his hand, and

found a great heat over the parietal bones, which so satisfied me as to the true nature of his complaint, that I immediately countermanded the bleeding apparatus, and ordered him to be removed into the cold passages. Having procured buckets of cold water, we kept a continual flow of it over his head and chest; but notwithstanding the intense cold of the day, this seemed for a long period to have no effect upon him. He laughed and knocked himself about with so much violence that it required seven or eight men to hold him; and his head and chest, particularly the top of the head over the parietal suture, remained so hot, and the heat at these parts was generated so fast, that the cold water evaporated as if thrown upon anything warm.

Pursuing this treatment for an hour, his convulsive laughing altered to convulsive crying, which was the first symptom of a decided improvement taking place. His violence began to lessen, his incoherent talking was left off, and he began to place his hands upon the top of his head, as if in intense pain. The cold water to the head was still continued for half an hour longer, when he was quiet enough to have cold water offered him to drink. In a short time, about three hours from the time he was first taken, he was so far recovered as to know where he was, and to distinguish the persons about him. After having been made to walk about for a short time, he was rubbed dry, placed in bed, and soon fell into a sound sleep, being quite exhausted with his troublesome exertions. He awoke weak and tired; all that had occurred on the previous day was totally forgotten, and the time occupied by his fit was a blank in his existence. He had a little salts, hyoscyamus, &c. and I thought it prudent not to allow him to return to his business for two or three days.

The very term hysteria, derived from *ὑστέρησις*,—the uterus, marks the sex to which this disease usually belongs, and many eminent practitioners deny the possibility of its occurring in the male. In this case we have as strong an instance as possibly could occur in a woman. Although mankind is divided into two perfect sexes, every male is not equally masculine, nor every female equally feminine. Hence, in common conversation we talk of a masculine

woman, an effeminate man, meaning that the individual possesses the body of one sex, and more or less the mind of the other. The man who was the subject of this communication is small, weak, and effeminate, possessed of an excitable and susceptible mind, easily startled, and quickly terrified. In his sleep also he frequently talks, sings, laughs, rattles his chair by his side so as to make it unpleasant for any other person to be in the same room with him. I have been assured that he has been known to be a somnambulist; that one night he left his bed and took a walk; in his perambulations, however, he met with a sentinel on guard, who not knowing whether he was flesh and blood, or only some departed spirit risen from the church-yard, on which a part of the Bank is built, stamped his foot, and struck his musket violently, which caused him to return to bed without knowing any thing that had occurred.

A person in hysteria never meets with any compassion, all persons thinking it is in a great measure at the power of the patient to have or not to have a fit, as it best suits their purpose. These notions are not only in part correct, but are practically good, in all cases of slight hysteria; but for the more violent ones the doctrine is by no means safe. The patient is frequently left so feeble, after a fit of the violence that I have described as occurring in this man, that the slightest exertion or excitement, for many days, will cause a return, and the danger of a relapse is generally proportionate to the degree of weakness produced by the first paroxysm. Hence the extreme danger of bleeding in these cases; for although it may immediately bring the patient to his senses, it depresses an already too much depressed system, and the person will be ill for weeks or months, with the risk of relapsing into hysteria from the slightest excitement. In cases where bleeding has been practised, the only thing that the medical man can do is to enjoin absolute quiet; no noise must be allowed in the room; nothing must disturb this highly excitable nervous system. What, then, ought to be the treatment of a person in hysteria? The state of the patient sufficiently indicates; for if we make a careful examination, we find that the top of the head is burning hot. In

mild cases the patient feels the greatest oppression at that place, and the hair even sometimes falls off to a great extent in that situation. The feet, on the contrary, are generally icy cold, so that it appears that the body, from some cause, is unequally supplied with heat, whilst the pulse indicates nothing remarkable in the circulation. If, in hysteria, we apply heat to the cold parts of the body, and cold to the hot, we at once set right that which appears to be wrong. I never knew in any case this method fail, though in some, as in the one now detailed, it is very difficult to effect that object. The power of evolving heat was so great, that it required many buckets of water poured over the head and chest, before the head was in any degree cooled. Heat was not applied to the feet of this man, because his extreme violence rendered that troublesome.

In most slight cases, a few drops of æther poured on the top of the head will instantly suffice to relieve the sufferer, and by repeating this the moment the patient feels that a fit is likely to supervene, the habit will be broken, the system will forget to have a fit, and eventually the hysteria tendency will be cured.

To the physiologist, the peculiar state of the patient presents many curious points. Although the state of the mind, in relation to its power over the body, as well as to its consciousness of external objects, is most singular; in a subsequent fit, of which I shall presently make mention, this man appeared to have some knowledge of what he saw. The moon was shining bright, which he observed, and frequently made allusions to it, though on his recovery he was utterly ignorant of all that had occurred during the fit. In other cases the imagination seems greatly excited, and the person seems to perceive distinctly things that have no existence. Some time ago I attended a young lady in one of these hysterical fits, who was making a drawing with a pencil upon the sheets, of the head "of a funny little man she saw in the moon," though on her recovery she would never even believe that she could be so "ridiculous," nor could she credit her other extraordinary fancies.

But let us return to our male patient; for we may naturally expect, after a fit so violent, others would follow, and I

used to ask him, nearly every time I came in contact with him, whether he had been again troubled, but still he remained perfectly well till the evening of the 27th of December last, when I was again summoned to attend him, as he was in the same state exactly he was in the previous year. On repairing to the spot I found him extremely violent, requiring eight or ten men to prevent him from dashing his head against anything that might happen to be in his vicinity. He was immediately removed into the external air, and the cold water treatment pursued in precisely the same manner as before. He required many buckets of water to cool him, whilst the bystanders were already too cold. The steam came from his head in the same way; in fact there was nothing worthy of remark in this fit more than in the one that had preceded, except that he had been partaking of the gaieties of the season, and although usually a very temperate man, he had taken a small quantity of porter and spirits more than usual. The immediate exciting cause of this fit seems to have been derived from his companions having joked him about some trifling matter; otherwise no further reason could be given. In about two hours and a half he was sufficiently recovered to drink cold water, which rallied him to such an extent that in a short time more he was enabled to be placed in bed: an emetic was then administered to him, to clear his stomach, and after its operation he speedily fell asleep.

The next morning he awoke weak and tired, but was enabled to walk two miles to his own home. He again went to bed, and slept for some time, after which he had a little magn. sulphatis, with hyoscyamus, and was sufficiently well to return to his work on the third day, although still weakly.

Having determined to send the account of this man's fit to the *MEDICAL GAZETTE* last year, I was desirous to see whether he would have any repetition of his malady. Having found a return after a year and two days, I have sent the account of the two fits, both of which, although occurring in the male, were more violent than we generally witness in women.

*Note.*—Up to the 27th Feb. he has had no return of his complaint.

7, Finsbury Circus, Feb. 27, 1842.

## ARTIFICIAL ANUS.

*To the Editor of the Medical Gazette.*

SIR,

CONCEIVING that the following subject may prove interesting to the readers of the *MEDICAL GAZETTE*, I beg to offer it, at your disposal, for insertion in the pages of your widely circulated journal; together with a brief outline of the results of all the cases in which the operation of artificial anus "*par le procédé de Callisen modifié*" has been performed by Dr. Amussat.

I remain, sir,

Your obedient servant,

JOHN CHARLES PARROTT.

Paris, Feb. 21st, 1842.

In your valuable periodical for April, 1841, I find a very lengthened and explicit statement, by Mr. Erichsen, of the two first cases in which the operation, proposed by Callisen, for relief of retention of the *fæces*, and modified by Dr. Amussat, was performed. Since Dr. Amussat's communication, read at the "*Académie de Médecine*" in October, 1838, concerning the operations of artificial anus, which he had already successfully performed in the left lumbar region, without opening the peritoneum, he has had several others of the same kind, with this difference, that in three of the cases the operation was in the right lumbar region, but at the same time without injury to the peritoneum. The results of four cases, together with an account of one operation performed according to the method of Littre, have been published by Dr. Amussat, in his "*Mémoires sur la possibilité d'établir un anus artificiel dans les régions lombaires, sans pénétrer dans le péritoine.*" In the month of November last, Dr. Amussat had occasion to perform, for the fifth time, the operation of artificial anus by the same method. With the exception, however, of the case I intend presently to detail, all the subjects of the above operations were persons far advanced in life, the diseases under which they laboured, and for which the operation was imperatively called for, having been, in three of the instances, scirrhus affections of the superior part of the rectum, and in the remaining cases the autopsy alone sufficed to discover the nature as well as the seat of obstruction.

It would be superfluous on my part, after the very recent observations which have fallen from Mr. Erichsen, to enter now into any description either of the surgical anatomy of the parts concerned, or of the *modus operandi*. Those, however, who may feel interested in this subject I must refer to the *Mémoires* published by Dr. Amussat, which are throughout eminently characterised by close and unremitted investigation. In these elaborate dissertations, he has fully and candidly stated every fact which may tend to weigh for or against the operation.\* It would also be, at the same time, quite impossible to insert, in this limited space, any considerable portion of the facts connected with this operation, or of the circumstances which may lead to the necessity of its performance; still I trust that the simple brief statement of the following cases, without any comments upon them, will clearly point out its paramount utility in similar predicaments.

CASE I.—Madame D. *æt* 48.—Complete obstruction of the sigmoid flexure of the colon, from the existence of a large pelvic tumor, the nature of which could not be determined. Obstinate constipation had existed for twenty-six days. *Stercoral tympanitis*. Artificial anus established June 2nd, 1839, by opening the left lumbar colon, without injury to the peritoneal sac.

*Result.*—This patient lived for a period of five months, when she was attacked by peritonitis, produced by the progress of the cancerous affection (for the tumor was only ascertained, on making a post-mortem examination, to be of a malignant character), which had caused the complete obliteration of the lower part of the intestinal canal. All the signs of a recent attack of acute peritonitis were found. The anus, which had been established in the left lumbar region, was most distinctly formed.

CASE II.—Monsieur T., *æt* 62.—The disease consisted in scirrhus vegetations of the internal surface of the upper part of the rectum, which had produced a complete obstruction to the exit of the *fæces*. The same operation was performed, as in the first case, on

\* The first *Mémoire* was published in 1839, the second in 1841, and may be procured at the library of H. Baillière & Co. Regent-street.

the 14th of July, 1839. The patient had no stool for eight days.

*Result.*—The patient (who has been living at Rouen since the month of August, 1839) is now perfectly convalescent. The last account which Dr. Amussat received of him was of a most satisfactory description. The artificial anus is well formed, and gives passage to the fæces very regularly. The carcinomatous affection of the rectum does not appear to have made any perceptible progress. Occasionally, by aid of injections practised from above (that is, from the artificial to the natural anus), the liquid escapes by the rectum, possessing a decidedly foetid odour. He is enabled to take daily exercise. Appetite is very good. The process of digestion is not at all interfered with, and he is gaining strength rapidly.

**CASE III.**—Madame Bollman, æt. 47.—Retention of fæces for thirty days. No appreciable cause could be ascertained. Vomiting of fæculent matter had existed for several days. An operation was performed on the 8th of May, 1840, according to the method of Littre, by opening the cæcum in the iliac fossa.

*Result.*—The patient died in twenty-four hours. Acute peritonitis had taken place. The seat of stricture was found to exist at the junction of the transverse with the descending portion of the colon, in which a portion of the vertebra of a bird had become impacted. Twelve hours after the operation, the edges of the wound had already assumed a livid aspect, and Dr. Amussat was fearful of the approach of gangrene, which has been known to happen in persons who were subjected to similar operations. The uncertainty as to the seat of obstruction, and the absence of positive signs to show that the colon was distended from this side, induced Dr. Amussat to proceed according to the method of Littre.

**CASE IV.**—Madame B., æt. 50.—Complete occlusion of the intestinal canal. Insuperable constipation had existed for forty days. Impossibility to discover either the nature, seat, or cause, of the retention of fæcal matter. Operation performed in the right lumbar region upon the ascending colon, without opening the peritoneum, July 3rd, 1841.

*Result.*—Since the operation, now more than eight months, the patient

has continued in the most satisfactory state. The artificial anus has been for some time firmly established. The evacuations are not involuntary, as one might be inclined to suppose, but, on the contrary, injections are required to facilitate the escape of the fæces. The latent affection, which has necessitated the establishment of an artificial anus, does not appear of a nature to compromise, at least for a long time, the success of the operation. This patient I was kindly permitted to visit a few days ago. I can fully corroborate the above statement.

**CASE V.**—Madame Legrand, æt. 60. Cancerous affection of the superior portion of the rectum. Complete obstruction to the passage of the fæces had existed for forty-five days. Artificial anus established in the right lumbar region, without opening the peritoneum, upon the ascending colon, August 21st, 1841.

*Result.*—The patient died ten days after the operation. The cause of death was found to depend on the ulcerative process, which had taken place in the diseased portion of the bowel. The mucous membrane of the small intestines exhibited, in several points, patches of inflammation. The patient had, two days prior to her decease, passed fæces through the natural anus; and, at the time of the autopsy, the finger could be readily introduced through the strictured portion of the gut, which, prior to the operation, was totally impracticable. No traces of peritonitis were found to exist.

**CASE VI.**—Monsieur Cogniart, æt. 57.—Retention of the fæces for thirty-three days. Cause of obstruction attributed to the existence of a large tumor in the left iliac fossa, supposed to be of a malignant character. Stercoral vomiting had commenced on the morning of the operation, which was performed in the right lumbar region, in November, 1841.

*Result.*—This patient I had the opportunity of seeing, in company with Dr. Amussat, a few weeks after the operation. Nothing could exceed the satisfactory manner in which the patient had throughout progressed. The artificial anus, by aid of tepid injections every other day, gave passage to the fæces very regularly. The patient is enabled to sit up during the greater portion of the day, and his ap-

petite was excellent. He left Paris, to reside in the country, shortly after. Dr. Amussat has since then received a letter from the medical man in attendance, in which he speaks of the rapid progress the patient is daily making. The cicatrization of the wound is entirely effected.

**CASE VII.**—The last case, of which I purpose to enter more fully into detail, is of a most deeply interesting nature:—

A woman, æt. 30, of tolerably robust and healthy constitution, who has been married some years, and already been the mother of two children (both of whom are dead), was delivered of her third child on the afternoon of Thursday, January 20th, 1842. She was attended in all her labours by a midwife. Nothing abnormal, however, occurred during the birth of any of the children. At the lapse of some hours after the delivery of her third child (an apparently stout and healthy-looking boy) it was observed by the midwife that there existed some impediment to the exit of the fæces, twelve hours having now elapsed, and no meconium been voided. A surgeon was immediately sent for, who, on examination, found that the obstruction was owing to the presence of a cul de sac about an inch and a half from the anus: the latter appeared well defined. A small silver female catheter was introduced, which, however, directly met with considerable resistance. The child was then taken to the "Hôpital de Clinique," when M. Larrey, having tried without success the introduction of the catheter, plunged a trocar (as was believed) into the cul de sac. Slight bleeding ensued on the withdrawal of the instrument, but no meconium escaped. The child was at length brought to Dr. Amussat on Saturday, January 22nd. He was then just forty-eight hours old. The countenance presented a dark, suffused appearance. The abdomen was hard and much distended. There had been frequent vomiting since birth. Pulse very frequent and feeble. Respiration performed with great difficulty. Urine had been freely voided, but was exceedingly turbid. No meconium had yet passed. A small bougie was now introduced, carefully avoiding any force, to the extent of about an inch and a half, when its progress was arrested by some resisting substance. On the in-

strument being inclined more posteriorly an opening was discovered, in which the bougie easily passed to the extent of four or five inches. This was very evidently a false passage. Dr. Amussat now examined with his little finger, with which he enlarged the opening previously made by the instrument. The obstruction was soon recognised. It was soft, somewhat elastic, and smooth on its surface, but did not give the impression of an intestine distended with meconium. The introduction of the index followed that of the little finger, but nothing indicated the presence of the large intestine. Dr. Amussat was of opinion that about two inches from the anus there existed an interruption of the rectum, the calibre of the gut being at this point totally obliterated, but that the inferior portion of the bowel, together with the sphincter, presented nothing abnormal. It appeared, however, to Dr. Amussat and to all that were present, after a very careful examination, totally impracticable that an artificial anus could be established either in the anal or coccygeal regions, and he therefore determined at once to open the colon in the left lumbar region.

The child being placed on his right side, a transverse incision, about two inches in length, was made midway between the crest of the ilium and the last false rib, commencing at the external border of the sacro-lumbalis and longissimis dorsi: the subjacent textures having been divided, the cellular and adipose tissue covering the kidney and colon was exposed. This was now, after a long and careful dissection, divided, after a great deal of uncertainty. The lower extremity of the kidney was fully exposed to view, but the intestine could not yet be recognised. The incision was, therefore, enlarged backwards and downwards (with an artificial light, the shutters having been closed), and Dr. Amussat saw (for his feeling did not afford him any certain indication) something of a violet colour, which he judged to be the small intestine, placed outside, and before the kidney. That was pushed backwards, and the colon at length detected. Two tenacula were now introduced longitudinally, one from above downwards, the other in a contrary direction, in order to prevent any retraction of the bowel, and a longitudinal incision after-

wards made. A considerable quantity of gas and meconium escaped. The edges of the opening in the intestine were fixed to the integuments by means of three sutures, and tepid injections administered. The hæmorrhage which occurred during the operation was easily suppressed by means of torsion. The artificial anus was now covered by a hot cataplasm, and the child removed home.

Monday, January 24th.—Since the operation no untoward symptom has occurred. There is little or no febrile excitement. The artificial anus appears well formed. The cataplasms, when removed, are always covered with fæculent matter. The integuments adjacent the wound are somewhat œdematous and reddened. Nothing has passed per rectum.

28th.—Continues much the same. The wound presents already a healthy granular appearance. The child takes the breast very well, and is perfectly tranquil. The fæces continue to pass well through the artificial anus. Abdomen quite free from distension.

February 1st.—The artificial anus appears firmly fixed to the wound, which presents a healthy aspect. The evacuations, which are of a liquid consistency, take place abundantly. The abdomen is soft, and insensible to pressure. Sutures came away yesterday. The child is quite free from any febrile symptoms, and takes its nourishment with avidity.

4th.—Continuing to progress very favourably. In the left iliac fossa there is a remarkable projection observed whenever the child cries, or when the fæces are being expelled. It appears to be a distended intestine.

7th.—Upon Dr. Amussat's visiting the child to-day, he found that there had been no evacuation for forty-eight hours. The abdomen was much tumefied, and painful on pressure. Urine had been voided freely. Bougies were introduced into the artificial anus, and injections afterwards made. A large collection of fæculent matter escaped, and the child became immediately more composed. A small wax tent to be kept constantly in the anus, attached by threads.

9th.—Much improved. The fæces, which are now of a more solid consistency, escape readily through the artificial anus. Tepid injections admi-

nistered every twenty-four hours. The child appears more animated, and every thing predicts a speedy convalescence. The projection in the iliac fossa still exists, but does not occasion any apparent inconvenience.

It would be tedious to dwell upon the minute reports of this highly interesting case. Since the time of the operation four weeks have now elapsed, and nothing can exceed the satisfactory condition of the young patient. The wound is perfectly cicatrized. Defecation is performed with the greatest facility. A small tent is kept constantly in the artificial anus, which prevents any closure of the opening. The child is evidently as well developed as any other of the same age.

From this last case we may reasonably infer that the operation proposed by Callisen, and modified by Amussat, is applicable in children as well as we find it is in adults, and that, alike in all, the opening in the intestine is effected without injury to the serous membrane of the abdomen.\* I know that many surgeons are still incredulous upon this subject, their objections against the performance of this operation being founded upon the impossibility of avoiding the peritonæum. But have we not conclusive proofs that it can be safely practised externally to the peritonæal sac, and do not the above striking examples of success afford us additional evidence in favour of the practice? Again, in one of the above detailed cases, where death took place, the autopsy has fully verified the correctness of Dr. Amussat's views.

In order to arrive at some definite conclusions, as to the merits or advantages of the respective modes of operations of Littre, and Callisen, modified, it may be useful to subjoin here some statistical account of the cases in which the plan of forming an artificial anus has been adopted. The most correct, and, perhaps, the only authentic account published, is contained in the first *Mémoire* of Dr. Amussat, a copy of which I have drawn up. (See following page.)

We have, I think, alas! too many examples to require further proof of the danger which attends it. Although at present the instances in which Dr.

\* Dr. Amussat told me that of six new-born children which he examined after death, in only one of these existed a meso-colon.

Jan. 1842	Amussat	Child	48 hours	Interception of rectum	Do.	Living.	

Amussat's method has been adopted are not very numerous, yet in comparing the results of the two modes of treatment, the great superiority of the latter is, I think, placed beyond a doubt. By the one process, the peritoneum receives no injury; by the other it is opened twice; a fact which seems to call for the rejection of Calisen's method altogether.

## EVACUATION OF FLUID FROM THE THORAX

BY MEANS OF THE COMMON GROOVED NEEDLE.

*To the Editor of the Medical Gazette.*

SIR,

I was led by accident, some time since, to the method of drawing off fluid in cases of effusion into the thorax, which I have lately found useful in cases of abdominal dropsy. The plan is so simple that I dare say it may be followed already by many persons, but as to others it may not have occurred, I think it right to offer the suggestion through the medium of the *MEDICAL GAZETTE*.

During the use of the common grooved needle for exploring the chest, on ascertaining positively the presence of fluid, previous to paracentesis, it happened on one occasion, at the Bristol Infirmary, that so large a quantity of fluid passed readily through the instrument as to preclude the necessity of any further operation. As paracentesis of the thorax, by means of a trocar, is much more painful than the introduction of the needle, and is sometimes followed by troublesome results, I determined to try for the future whether the same success would follow the use of the latter instrument. In many instances this was found to be the case, but occasionally the fluid was too thick to run off through so small a passage. This was obviated by getting a needle made with a somewhat larger groove. Such a needle has been used with perfect success in every case of the kind that has fallen under my observation during the last year or two, and the number has been considerable. The pain is so slight, that a patient, who has once experienced it, totally disregards it, in the desire of that relief which he has obtained, and has called eagerly for

a repetition, to which he has submitted as to a trifling annoyance.

I have now a patient in the infirmary, a female aged fifty, lately affected with ascites. She had been twice tapped by means of the trocar. When she was full a third time, I proposed a third paracentesis. She earnestly deprecated it on account of the pain which she had suffered from the trocar on a former occasion. It occurred to me to try the grooved needle, and it was accordingly passed through the linea alba, and the patient was relieved. It is worthy of note that the effusion of fluid has not returned. The woman, although previously in a state of very broken health, appears now, after the interval of some weeks, to be convalescent. I think it just possible that paracentesis by the needle may be less favourable to a return of effusion in cases of ascites, as it is known to be in those of hydrocele. Whether this may be the fact or not, I am sure that great advantage will arise to patients if the use of the needle be substituted for that of the trocar in tapping both for ascites and for hydrothorax. I am persuaded that the practice of deferring paracentesis in the former disease till all other means, many of which are very exhausting ones, have been long tried, and have entirely failed, is one principal cause of the frequent return of effusion. The use of the needle affords so much greater facility that the operation will cease to be dreaded, and will be performed more easily, and, if so, with more frequent ultimate success.—I remain, sir,

Your faithful servant,

J. C. PRICHARD, M.D.

Physician to the Bristol Infirmary.

Bristol, March 3, 1842.

## POOR-LAW FREAKS.

It is to be hoped that the exertions of the press have been attended with a certain degree of success, and that we

are about to witness some mitigation of the late enactments against the poor. Malthusians of the better sort—that is to say, those who are but lukewarm disciples of the great economists—will admit some improvements in the dietaries, and other approximations to humanity, which do not threaten totally to subvert their darling scheme, of teaching the poor “to rely on their own resources;” while those sterner theorists, who are alike inaccessible to pity and to reason, will still see the necessity of yielding something, though they may probably qualify their sacrifices with the ungracious name of concessions to public clamour. In order, however, that the slight vantage-ground gained by humanity may be maintained, it is necessary that the proceedings of the Commissioners and their subalterns should be observed with undying watchfulness—from the conclave of Somerset House down to the nurses of a Union bastille. Without this unceasing superintendence there is the most imminent danger that the harshest misdeeds of the new system may be revived with double severity.

Meantime, it may be useful to dwell upon the abuses introduced by the working of the new law into the medical relief of the poor; abuses so enormous and so shocking, that had they continued unchecked, myriads would have been practically left without aid in their sickness. Those who wish to know what is the condition of the indigent classes when left to their own resources, may consult the admirable essays of Dr. Alison on the state of the poor in Scotland, and the communication of Mr. Bell in our last number but one; and may thence learn the acmé of perfection to which the preaching and practice of our economists alike tended.

Many of the examples of the unrestrained working of the system in its most flourishing state are to be found

in a pamphlet published by the Provincial Medical Association, which is now before us\*.

The Lincoln Union was formed in 1836-7, out of 89 parishes, with a population of 30,230. The poor had been previously attended by fifteen or sixteen practitioners, whose united salaries amounted to £350 per annum. When we consider that, even according to the estimate of Assistant-Commissioner Gulson, the extent of this Union is 20 miles by 16 or 17—an estimate which is below the ascertained measurement—it will be allowed by every impartial person that this sum is far less than justice and humanity require: no one of average common sense would expect the poor of so large a district to be properly attended at such a rate. With the Guardians, however, *quocunque modo rem*, “save at any cost,” was the one ruling maxim; and they “fixed the medical salaries at £270 for the whole Union, which sum was declined by every practitioner to whom it was offered.”

As the medical practitioners and the Board of Guardians could not come to terms, the latter obtained the services of a Mr. Shireff, who took the whole of the Union for £200, for one year.

Whether a practitioner with so large a district under his care would improve much in the practice of physic and surgery, we know not; but it is clear that he would have ample opportunities of learning horsemanship and topography, did his salary but allow him to keep a sufficiently large stud.

This curious experiment in racing and doctoring, or running a practitioner against time, does not seem to have

---

\* The administration of medical relief to the poor under the Poor-Law Amendment Act, and other legislative provisions for the public health, considered in the reports of the Poor-Law Committee of the Provincial Medical and Surgical Association. To which are appended certain clauses suggested for insertion in the contemplated bill for the amendment of the Poor-Laws. London, 1842.

been relished either by the poor or the rich in the Lincoln Union. The former were so cautious, that, with the exception of the sick in the workhouses, Mr. Shireff was for six or seven weeks without a pauper patient on his list; and he confessed that, for the first year, their number never exceeded fourteen. The rich, too, patronized him but feebly; so that, in spite of the support of the Guardians, who narrowed his district, and allowed him to dismiss his assistant without diminishing his salary, he was obliged to leave the Union in the November of the following year.

Since this event various changes have taken place, and at present nine medical officers are employed, whose united salaries amount to £260 per annum. Mr. Gulson says, pleasantly enough: "I think that, in this instance, no Board of Guardians could be shewn to be more anxious to do the best that could be done for the poor."

If humour has been justly defined to be that kind of wit which makes others laugh, without laughing itself, the Assistant-Commissioner must be allowed to be a proficient in it. Next comes the Bridgewater Union *infelicitis memoris*. Who can forget the bad eminence attained by this Union among all the mismanaged districts in England—the shabby offers of the Board—their refusal to fulfil the engagements they had made with their medical officers—and their appointment of a candidate who was not a surgeon? Above all, who can forget the Bridgewater Union Workhouse, where the poor were mowed down by disease and starvation, not singly, but in the gross?

And over them triumphant Death his dart  
Shook, but delayed to strike, though oft invoked  
With vows, as their chief good, and final hope.

The Aylesbury Union, containing forty parishes, and a population of 21,420, was originally divided into four districts, and supplied with only three medical officers; so that, in the remoter

parishes, poor persons suffering from acute and serious disease were literally unable to procure medical aid. A surgeon might have eight, or even twelve miles, to go to a case; nay, the officer who held two districts "might have been called upon, after accomplishing fourteen miles of this district [No. 2,] to travel nineteen miles through No. 4."

Curiously enough, if any thing could be curious to one who has studied the workings of the New Poor-Law, Assistant-Commissioner Wade "was known to suggest that one medical man could undertake the whole duty; the extent of the Union being twenty-three miles by fifteen."

When the mean offers of Boards of Guardians are refused, they have commonly threatened to bring down medical men from London; but it is to be hoped, for the sake of the respectability of the profession, that these intruders have rarely succeeded in establishing themselves in these mismanaged Unions. It is painful, however, to find any practitioner reduced to want, even by compliance with the whims of our starvationist sages, as in a case narrated in the pamphlet of the Provincial Association. In December, 1838, a woman, whose manner bore witness to her education, and who was the wife of a surgeon, applied for relief at the meeting of Guardians in St. George's Union, Southwark. Her husband "had been one of the medical attendants to a country Union, comprising twenty-five parishes; and for his services the Poor-Law Commissioners had awarded a salary of £30 a year (?) on which, it appears, he and his wife starved."

In the Eton Union two strangers were brought down by the advertisements of the Guardians. One of them was dismissed by the Board, after a coroner's inquest on a pauper whom he attended. During the unavoidable absence of the other stranger, the sick poor applied for relief to a druggist, who

allowed a dislocated shoulder to remain unreduced for two nights and a day, till it was charitably reduced by one of the established practitioners.

The Faversham Union was formed of twenty-five parishes, which had been attended by eight practitioners, whose united salaries amounted to about £500. Sir Francis Head advised the Guardians to offer £250. They did so; but their proposal being declined by all the resident practitioners, the Guardians, nowise disheartened, advertised, and with the most splendid success.

"A perfect stranger, being at the time in prison for debt, applied for and obtained the appointment to the whole Union! He was without a horse or an assistant, and destitute of the necessary remedies and means of preparing them."

The Guardians, however, were wide awake to the advantage offered them by the indigent state of their medical officer: leave them alone for striking a bargain.

"In consequence of his inferior equipments, the Board reduced his salary to £225, thus incapacitating him still further for attending properly to his unfortunate patients."

Could Harpagon have done better?

"The complaints of the poor were loud and constant. Nevertheless the Guardians retained their medical officer until 1837, when, from increasing embarrassments, and inability to fulfil his engagements, he abruptly absconded."

Really, it is impossible to refrain from something like praise of the awkward and misplaced zeal of these unjust stewards. Could any one succeed in inspiring them with a spark of right feeling, their obstinacy in a bad cause might become ardour in a good one; and the dogged instinct with which they persevered in saving a few wretched pounds, might be turned into an unceasing struggle to lessen the amount of human misery. As it was, however, they stuck to their

friend as long as his shadow was to be seen in the Faversham Union.

"I know not, I care not, if guilt's in that heart,  
But I know that I love thee, whatever thou art!"

In the Hambledon Union, containing sixteen parishes, and 11,882 inhabitants, seven practitioners had been employed. The salaries and extra charges amounted to about £450 per annum.

This would not have been a very enormous remuneration for attending the poor in a district twenty miles by ten, with an area of about 106 square miles.

But *novus rerum jam nascitur ordo*; the Guardians offered £250 per annum, including midwifery; while the medical practitioners thought that midwifery should be charged extra, and no agreement could be made.

The Guardians accordingly took refuge in the columns of the newspapers, and obtained a tender frugal enough to make a Board's heart leap with joy; just imagine, a tender of £110 for the whole Union! The Guardians immediately gave the person £40 more than he asked; the next year they added £100 to his salary, and afterwards extra remuneration for midwifery, so that he finally had, and has, the very terms proposed by the former surgeons.

It would be satisfactory to know how many assistants, biped and quadruped, a man must possess, to enable him to do justice to the patients at every extremity of the Hambledon Union. But we must defer this inquiry to some future occasion.

---

## POOR-LAW.

### MEDICAL OFFICERS OF UNIONS.

*To the Editor of the Medical Gazette.*

SIR,

I BEG leave to hand the enclosed papers and accompanying letter from the President of the Royal College of Surgeons, upon the appointments, &c. of medical officers of Unions, under the Poor-Law

Amendment Act, for insertion, if you think fit, in the *MEDICAL GAZETTE*. I am, sir,  
Your obedient servant,  
THOMAS HOVELL.

Clapton, March, 21, 1842.

LETTER FROM MR. GUTHRIE.

MY DEAR SIR,—I transmit to you herewith a copy of the Medical Order of the Poor-Law Commissioners, with their explanatory letter accompanying it. You will perceive that the mode of obtaining the services of medical men by tender is abolished; and that they will, on the expiration of the present contracts, hold their places in future, subject only to death, resignation, or legal disqualification; and whenever, from circumstances, it may be necessary to ask publicly for the services of any physician, surgeon, or apothecary, the sum to be paid for such services is required to be stated; and as it must have been previously approved by the Poor-Law Commissioners, a return to the system of tender will be prevented; but which, without this check, would have been in all probability attempted.

You, and the Profession at large, will readily acquit me of having had anything to do with the qualification part of the order, amended as it is by the explanatory letter. It was my wish that the double qualification of Physician of any University or legally constituted College in the United Kingdom, and of Surgeon of any one of the three Royal Colleges of Surgeons, or of one of these surgeons being also a Member of the Society of Apothecaries, or in practice before 1815, should have been the qualification required by their order; the medical examination by the heads of departments of the public service being considered equal to that of the Examiners of the Society of Apothecaries, without reference to 1826, as stated in Article 4 of the Qualification Order. There appeared to be some objections to these propositions which the legal adviser of the Poor-Law Commissioners could not surmount; but Mr. G. C. Lewis, the only Commissioner then in London, was so sensible of their propriety that he offered to propose to the Secretary of State to see me with him on this particular point. In the meantime, the Secretary of State was pleased to transmit to me, in my official capacity, the heads of a bill for the improvement of the medical profession, which he intended to introduce into Parliament this session; and as this bill, if carried into effect, will settle the matter in a manner which will be highly satisfactory, it was not worth while pressing any further alteration at this moment on the attention of the Poor-Law Commissioners.

With respect to the rates of *extra* payment for surgical and midwifery cases, the

medical profession and the poor are greatly indebted to the kindness, the humanity, and the liberality of Mr. Lewis. The only point with which I have had nothing to do, is that which relates to the Consultation Certificate, and which will, of course, follow the fate of the other qualification clauses.

I understand the sum of twenty shillings to be justly claimed by the surgeon when the distance from his own house, in an ordinary case, exceeds two miles. The sum of forty shillings for difficult and protracted cases cannot, I think, be misunderstood.

The maximum area and population of medical districts are in progress of diminution; nevertheless a district of 15,000 acres, or a rural population of 15,000 persons, the quantities assigned by the order, are both one half too large for one medical officer; it being impossible that the sick poor can be justly and fairly attended to by him, although there may be many reasons why Unions or districts of this extent and population should exist. In all such cases, the medical officers should be multiplied; no one should be allowed to go more than three miles from his own door, if it can be avoided; and if there should happen to be eight, ten, or more parishes in any of these Unions, and a qualified practitioner can be found in every parish, he should be employed, and held responsible for his own conduct, but not for that of any of his coadjutors.

It is not, however, in my opinion, advisable for the members of the medical profession to interfere, or to give themselves any trouble on this subject, as it is one the Boards of Guardians will themselves correct, as soon as the remaining and the only grievance, as I venture to think, which really and seriously interests the medical men, is removed. That grievance is the absence of a principle, or the want of recognition by the Poor-Law Commissioners of a principle, by which the remuneration of medical practitioners for their ordinary services shall be regulated.

There is no part of this subject that I have not thoroughly investigated from the best possible sources of information; and when I stated to you in my last letter that the total sum paid to the doctors was not half what it ought to be, I stated less than the truth, for in many parts of England it is not one third, although in others nearer London it sometimes approaches the sum which ought to be paid according to those computations which the Poor-Law Commissioners do not disavow, and which are so often alluded to in the reports of their own assistant-commissioners, and particularly in those of my very able friend, Colonel Wade.

A person not conversant with this subject will naturally express surprise that any man, or set of men, should wish to work out de-

tails without a guiding principle; because such person, or indeed any one acquainted with the ordinary forms of business, must be aware that it cannot be done in a satisfactory manner; for where many parties are concerned, disagreements must necessarily take place, which would not occur if a principle of remuneration were fairly established.

It is supposed that the Poor-Law Commissioners have the power of establishing this principle if they pleased so to do. It is, however, a point which I could not, consistently with that courtesy which is due to all public functionaries, press on Mr. G. Lewis; and I really cannot say whether they have the power or not; but if they have not, they ought to have it, and to exercise it; for nothing can be more unreasonable than for one Board of Guardians to be permitted to estimate the services of a surgeon at thirty pounds; whilst another Board, more liberal, values similar services at sixty; and a third Board considers the same services worth, and actually gives, a hundred.

These gentlemen form their estimate on no rule nor principle beyond their own good pleasure; and the situation of the apothecary, whose poverty, but not his will, forces him often to take a sum for his services which will not enable him to perform them. They are, therefore, not performed; and the poor have only the semblance of medical assistance, but not the reality, in many parts of the kingdom; and they never will have it until a principle of remuneration for medical services shall be laid down, and enforced by the Poor-Law Commissioners.

The mischief has been done by the boards of guardians, who have beaten down the doctors to such extent by the tender system, and the introduction of new persons, frequently incompetent as medical men, where the old ones have resisted. That the Poor-Law Commissioners do not like it, appears to me to make them act on any principle which shall have the effect of materially increasing the salaries of the medical officers; although by so doing they will secure to the poor the effective attendance of capable and humane practitioners.

I am aware that gentlemen of great ability have been often engaged by the boards of guardians as union doctors; but then they do not secure their effective services; they only obtain in the greater number of instances those of their apprentices or students, who are often utterly incompetent to fill their places; and some of these young gentlemen have made a merit with me, in my official capacity as president of the college, that they had for two or three years attended the poor without knowing any thing of anatomy, physic, or surgery, than they could pick up behind the counter of an apothecary's or druggist's shop. I did intimate to the Poor-

Law Commissioners that no assistant should be allowed to act for his principal unless he possessed at least one qualification, either from the College of Surgeons or from the Society of Apothecaries; but I did not feel I should be justified in urging this point on their attention, unless their order was to be accompanied by another, which should so augment the salaries of the union surgeons as to enable them to meet this additional expense.

Two principles of remuneration have been proposed, and acknowledged by the Poor-Law Commissioners. One is to allow the doctor from three pence to six pence a-year for each person, sick or well, in every rural district; and from three halfpence to two pence in every town district. Three pence per head when the rural district is small, four pence halfpenny when larger, and six pence when it is extensive, and the population is dispersed.

It is a fair and honest proposition, and beyond all comparison the best, because it conceals nothing, and admits of the most prompt and perfect assistance being given to the poor. There are some few slight difficulties attending its execution, but they cannot be maintained as valid objections before any competent investigation. The real objection is one with which the doctor has no concern. It is purely theoretical, and has been disproved by the experience of the last seven years. Wherever there is a workhouse it should be paid for separately at the rate of ten pounds a-year for every fifty persons, and of fourteen per cent. for medicines; so that the salary of a medical officer, for attending daily a workhouse containing fifty persons, and finding them in medicines, &c., of all kinds, would be seventeen pounds a-year.

The second principle of a pauper list and a per case system, is that which has been selected by the Poor-Law Commissioners for recommendation to the Boards of Guardians, under head, "Mode of obtaining Medical relief by permanent Paupers," which applies only to such persons, but not to those who are not permanently paupers, numbers of whom must be attended by the doctor, and the Boards of Guardians are at liberty to pay for both sets of paupers in any way they please; and in one district in Lambeth opposite the seat of government and to the houses of parliament, the sum they have been pleased to allow, when duly divided, amounts to eight pence per head for each sick person.

If the Poor-Law Commissioners had stated in the medical order now issued that the combined reports of the various assistant Commissioners, and of the medical profession at large, had proved that a sum not less than two shillings and sixpence ought to be paid

for each person on the pauper list, and not less than six shillings and sixpence for each casual pauper, and had enforced such payments, as well as those which have been recommended for attendance on the workhouse, the subject would have been complete; the principle would have been carried out, the detail would have been perfected, and the Boards of Guardians would have had a just right to insist on the strict attendance of the medical officers, and that the poor should not be neglected.

I take the liberty of suggesting to the members of the medical profession that their efforts should be made to strengthen the hands of the Poor-Law Commissioners in such manner as will enable them to declare not only the principle of remuneration they are pleased to select, but also to carry out and enforce its details in a manner which shall be just and satisfactory to them. I believe they will best effect this object by prevailing on the various Members of Parliament of their respective towns and places to wait upon the Secretary of State for the Home Department, and to induce him to empower the Poor-Law Commissioners to abate the nuisance which their defective authority has occasioned.

If the gentlemen of the London district who have done the Vice Presidents and myself the favour to confer with us on these subjects shall wish it, I will present any two of them to the members for Middlesex, who will, I am satisfied, give them their best assistance.

The humanity, kindness, and charity, of Mr. Byng, and his desire to amend the condition of the poor, are proverbial. Their younger member, Colonel Wood, is not behind him in the same good feelings, and will support the members of the medical profession in every thing that is reasonable, right, and just; and my efforts, as long as I am permitted to make them, shall not be wanting in the proper and highest quarters.

I am, my dear sir,

Yours very truly,

G. J. GUTHRIE.

4, Berkeley-street, Berkeley-square,  
12th March, 1842.

T. Howell, Esq., Clapton.

## LETTER ACCOMPANYING GENERAL MEDICAL REGULATIONS.

SIR,

ONE of the most important subjects considered by the Select Committee of the House of Commons, which in 1838 enquired into the operation of the Poor Law Amendment Act, was the medical relief of the poor.

After examining numerous witnesses on

this subject, the Committee decided to recommend no legislation by Parliament on medical relief, but having expressed their opinion that the existing arrangements might in several points be ameliorated, and having indicated several improvements, they left the introduction of these and other alterations to the discretion of the Poor Law Commissioners.—(Report, p. 25.)

The Commissioners, having given the entire subject a mature consideration, fully stated their views upon it in their Report on the Further Amendment of the Poor Laws (31st of December, 1839), p. 73—81. They subsequently by a circular letter, dated the 6th of March, 1841, (see 7th Annual Report, p. 8), called the attention of the Boards of Guardians to their suggestions in this Report; and requested to be informed of the opinion of the Boards as to the expediency of adopting those suggestions.

The answers which were returned by the Boards of Guardians to this circular (which are partially abstracted in the Seventh Annual Report of the Commissioners, page 9—14,) shewed, however, that no extensive change in the existing arrangements was likely to originate with the Boards of Guardians. Accordingly, as much dissatisfaction continued to prevail amongst many members of the medical profession, and as little progress had been made towards carrying into effect some of the recommendations of the Committee, the Commissioners have thought themselves called upon to select the most important points of the subject, and to issue generally to the Unions such regulations upon these points as appear to be needful and prudent.

The following are the heads of the accompanying order:—

1. Tenders for medical attendance.
2. Qualifications of medical officers.
3. Maximum amount of area and population of medical districts.
4. Rates of payment of medical officers in certain surgical and midwifery cases.
5. Substitutes for Medical officers during their incapacity to act.
6. Arrangement for affording medical relief to permanent paupers without a special order in each case.
7. Continuance in office of medical officers.

The Commissioners subjoin some explanatory remarks upon the main provisions of the order.

Arts. 1 and 2 are intended to abolish the system of requiring tenders for the services of medical officers; according to the views of the Commissioners, explained in their Report on the Further Amendment of the Law, p. 76—8. These articles, however, do not prohibit advertisements for the services of medical officers, provided such advertisements specify the remuneration fixed

or approved by the Commissioners. It is the wish of the Commissioners that the competition of the candidates should turn upon their respective characters and skill, and not on the sum at which they may be severally willing to undertake the office.

Arts. 3—5 relate to the qualifications of medical officers.

The Commissioners think it desirable that every medical officer should possess both a medical and a surgical qualification, and therefore they have required the three sorts of double qualification which are specified in Art. 3, Nos. 1, 2, and 3.

With respect to the second qualification in No. 3, see 55 G. 3, c. 194 (the Apothecaries' Act).

The Commissioners thought themselves bound to consider the qualification stated in Art. 3, No. 4, as virtually a double qualification, according to the decision of the Court of Exchequer, in *Steavenson v. Oliver*, 8 Meeson and Welsby, 234. The qualification is limited to warrants or commissions, dated previously to 1st August, 1826; inasmuch as the Act of 6 G. 4, c. 133, (which brought persons possessing this qualification within the benefit of the Apothecaries' Act,) expired on that day.

Art. 4, provides a means by which a duly qualified medical man not possessing any of the four qualifications required by Art. 3, may, in case of necessity, be appointed a medical officer: and Art. 5 enables an exception to be made in favour of existing medical officers.

The Commissioners have limited the provisions of their order to qualifications proceeding from an English source. In case, however, any medical man possesses an English qualification of physician or apothecary, together with a Scotch or Irish surgical qualification, the Commissioners will consider such person as virtually possessing a double qualification; and they will admit him as an officer, (if otherwise fit for the office) under Art. 4, upon application from the Guardians for that purpose.

Arts. 6—9, relate to the maximum area and population of medical districts.

The Committee of 1838 expressed an opinion that the medical districts seemed to be in some instances inconveniently large, and that they should be of such a size as to admit of an easy access of the medical man to his patients. (Report, p. 25.) The Commissioners have constantly borne in mind this recommendation of the committee, and have already required the division of many medical districts which seemed to have too large an area. A considerable improvement has thus been already effected in many individual cases; but the Commissioners think that the time is now arrived when it is desirable for them to make a general regu-

lation on the subject, and they have accordingly inserted one in these articles, accompanied with such limitations and exceptions as the circumstances of the case appeared to require.

The Commissioners are aware that in many districts containing almost exclusively a poor population, even the limit of 15,000 persons may admit of a number of patients too large for the care of one medical officer; especially if the district consist partly of a town and partly of rural parishes. Under such circumstances, it would generally be practicable for the Guardians to divide the district between two or more duly qualified medical practitioners. In like manner it may happen that a district consisting of an area less than 15,000 acres may contain a large population, and that the Guardians may be able to divide it with advantage. The Commissioners therefore do not by the limits fixed in Art. 6 imply that no district is objectionable, or that every district will be sanctioned by them, which is within these limits.

With respect to Art. 9 it may be observed, that the measure of acreage adopted in Art. 6 cannot be applied to Wales, as there are no available means of obtaining the requisite information in that part of the country; and the Commissioners have accordingly prescribed for Wales a limit, not of area, but of distance, which, though less convenient, is the best which the case permits. Moreover, the physical circumstances of Wales, and the small number of resident medical practitioners, render it necessary to permit the formation of medical districts larger than those in most parts of England.

Art. 10—13.] It is the earnest wish of the Commissioners to carry into effect the recommendation of the Committee, that "the remuneration of medical officers should be such as to ensure proper attention and the best medicines," (Report, p. 25); and the Guardians will doubtless perceive that unless the medical officers be adequately remunerated, no vigilance on their part will suffice to secure proper attendance and medicines to the poor under his care.

The Commissioners still retain the opinions expressed in their Report on the Further Amendment of the Law, p. 78—80, and since repeated to the Board of Guardians in their Circular of March, 1841, as to the advantages of a joint system of fixed salary and payment per case for medical officers; and they will remark incidentally that unless a system of payment per case is adopted, the recommendation of the Committee that the medical relief should be a parochial and not a union charge (Report, p. 24) cannot be carried into effect.

The wide differences between the circumstances of different Unions, especially in respect of the density and character of the

population, render it, however, nearly impossible for the Commissioners to prescribe the universal introduction of this or any other mode of payment.

It appeared, nevertheless, to the Commissioners, that it was possible for them to furnish a universal scale of payment for the surgical and obstetrical services specified in Arts. 10—13; the nature of which is such that they might, under certain circumstances, be properly excluded from the salary of the medical officer, and be paid at higher rates than ordinary medical cases. The Guardians will thus be enabled to approximate to the views of the committee, by making these a parochial charge.

The operations enumerated in Art. 10, are intended to provide for cases of urgency (principally those arising from accidents), which cannot be sent to a public hospital with safety and propriety. The payments for operations are limited to operations on out-door poor, and do not include those performed in the workhouse. It appears to the Commissioners, that the continued attendance at the house of the patient in severe surgical cases, usually forms the most burdensome part of the extra service of the medical man: whereas the constant visits of the medical officer to the workhouse enable him to attend a patient in the workhouse without always making a visit for that express purpose. Moreover, when a patient can be removed to a workhouse, or when he has long been the subject of medical treatment in the workhouse, he may in general be removed with safety or propriety to an infirmary or hospital; and the Commissioners think it desirable that, where the distance or other circumstances do not present serious obstacles, paupers should enjoy the practised skill and combined judgment of the medical men usually connected with such establishments. While, therefore, the Commissioners would discourage the performance of important surgical operations in workhouses, they are ready to sanction any reasonable subscription to a hospital or similar establishment by a Board of Guardians for the Union.

The payments are intended to cover not only the operation, but also the attendances after the operation, which, in severe cases of this sort ought usually to be numerous; and, therefore, they are limited to cases in which the patient survives the operation more than thirty-six hours, and receives several subsequent attendances. Cases in which the patient does not survive the operation thirty-six hours, or in which he does not receive several subsequent attendances, may be included in the contract of the medical officer with the Guardians.

Art. 15.] If any medical officer has a partner or assistant, who is a duly qualified

medical man, he may name such partner or assistant under this article.

The medical officer will be considered by the Commissioners as responsible for the skill and diligence of the person named by him as a substitute.

Arts. 16—19 are intended to facilitate the obtaining of attendance and medicines by the permanent paupers; a class whose destitution is acknowledged, and which necessarily includes the most helpless portion of the community.

Art. 20, places the medical officer on the same footing with the other officers, as to the period of his office, unless such period be specially limited at the time of his appointment. It does not seem desirable to exclude the Guardians from the opportunity of improving the arrangements respecting medical relief as the circumstances of the several districts may permit, and therefore it is not advisable to deprive them of the power of limiting the period of the medical officer's services.

The Commissioners intend, in a short time, to issue a general order prescribing the adoption, by the medical officers, of the nomenclature, of diseases now in use under the authority of the Registrar-General, which will insure greater uniformity and precision of language in the returns made by the medical officers, and will furnish a convenient interpretation of many of the more obscure scientific names of diseases.

(Signed by Order of the Board,)

EDWIN CHADWICK, Secretary.

Poor-Law Commission Office, Somerset House, March 12, 1842.

*The Clerk to the Guardians  
of the Union.*

## SCHEDULE ISSUED BY THE POOR-LAW COMMISSIONERS.

*To the Guardians of the Poor* of the several Unions named in the schedule hereunto annexed.

To the clerk or clerks to the justices of the petty sessions, held for the division or divisions in which the parishes and places comprised within the said Unions are situate.

And to all others whom it may concern.

WE, the Poor-Law Commissioners, in pursuance of the authorities vested in us by an Act passed in the fifth year of the reign of His late Majesty King William IV. intituled "*An Act for the Amendment and better Administration of the Laws relating to the Poor in England and Wales*," do hereby order, direct, and declare, with respect to each and every of the unions named in the schedule hereunto annexed, as follows:—

*Tender.*

Art. 1.—It shall not be lawful for the Board of Guardians of any of the said Unions, by advertisement, or other public notice, printed or written, to invite tenders for the supply of medicines, or for the medical attendance on any of the paupers within any such Union, unless such advertisement or notice shall specify the district or place for which such supply of medicines and such attendance is required, together with the amount of salary or other remuneration fixed or approved by the Poor-Law Commissioners, as the consideration for such supply of medicines and such attendance, or either of them.

Art. 2.—All salaries or other payments to any medical man, fixed by any of the said Board of Guardians; and every contract made by any of the said Board of Guardians with any medical man, in pursuance of any advertisement or other notice, inviting medical men to tender their services at a sum or sums not named in such advertisement, or notice, shall be deemed to be fixed or made in opposition to the rules and regulations of the Poor-Law Commissioners in force in this behalf; and all payments made towards such salary, or in fulfillment of such contract, shall be disallowed in the accounts of the parties authorising or making the same.

*Qualification.*

Art. 3.—It shall not be lawful for any of the said Board of Guardians to appoint any person to be a medical officer, unless such person, at the time of his appointment, shall possess one of the four following qualifications; that is to say,—

1. A diploma from the Royal College of Surgeons in London, together with a degree in medicine from an University in England, legally authorized to grant such degree, or together with a diploma or license of the Royal College of Physicians of London.

2. A diploma from the Royal College of Surgeons in London, together with a certificate to practise as an apothecary from the Society of Apothecaries of London.

3. A diploma from the Royal College of Surgeons in London—such person having been in actual practice as an apothecary on the first day of August, one thousand eight hundred and fifteen.

4. A warrant or commission as surgeon or assistant-surgeon in Her Majesty's Navy, or as surgeon or assistant-surgeon or apothecary in Her Majesty's Army, or as surgeon or assistant-surgeon in the service of the Honourable East India Company, dated previous to the first day of August, one thousand eight hundred and twenty-six.

Art. 4.—Provided always, that if it shall not be practicable for the Board of Guardians

to procure a person residing within or near the district in which he is to act, and duly qualified in one of the four modes recited in Art. 3, to attend on the poor in such district, or that the only person resident in or near such district, and so qualified, shall have been dismissed from office under the seal of the Poor-Law Commissioners, or shall be judged by the Poor-Law Commissioners to be unfit or incompetent to hold the office of medical officer, then and in such case the Board of Guardians shall cause a special minute to be made, and entered on the usual record of their proceedings, stating the reasons which, in their opinion, make it necessary to employ a person not qualified as by Art. 3.; and shall forthwith transmit a copy of such minute to the Poor-Law Commissioners for their consideration; and the Poor-Law Commissioners may, if they fit so to do, permit the employment by such Board of Guardians of any person duly licensed to practice as a medical man, although such person shall not be qualified in one of the four modes required by Art. 3.

Art. 5.—Provided also, that it shall be lawful for the Board of Guardians, with the consent of the Poor-Law Commissioners first had and obtained, to continue in office any medical officer duly licensed to practise as a medical man already employed by any such Board of Guardians, although such medical officer may not be qualified in one of the four modes required by Art. 3.

*Maximum area and population of medical districts.*

Art. 6.—It shall not be lawful for the Board of Guardians to assign to any medical officer, to be by them hereafter appointed, a district which shall exceed in extent the area of fifteen thousand statute acres, or which shall contain a population exceeding the number of fifteen thousand persons, according to the then last enumeration of the population published by authority of Parliament.

Art. 7.—Provided always that where any medical officer may on the day on which this order shall come in force, hold any district exceeding either in area or population the limits fixed in Art. 6, and such medical officer may have been appointed to such district for any time not exceeding twelve calendar months, he shall continue to hold his office, if not otherwise removed therefrom, up to the expiration of the time for which he was so appointed; but that where any medical officer shall have been appointed to any district exceeding the said limits in area or population for any space of time longer than twelve calendar months from the day in which this order shall come into force, the continuance of such officer in his office shall cease and determine on the twenty-fifth day of March, one thousand eight hundred and forty-three, or

whenever the term of such appointment may expire, whichever shall first happen.

Art. 8.—Provided also, that if it shall be impracticable for the Board of Guardians to divide any Union into districts containing respectively an area and population less than is specified in Art. 6, then and in such case the Board of Guardians shall cause a special minute to be made, and entered on the usual record of their proceedings, stating the reasons which in their opinion make it necessary to form a district exceeding the said limits, and shall forthwith transmit a copy of such minute to the Poor-Law Commissioners for their consideration; and if the Poor-Law Commissioners shall signify their approval thereof to such Guardians, then, and in such case, but not otherwise, such Guardians may proceed to appoint a medical officer for the said district.

Art. 9.—Provided also, that the limits of fifteen thousand statute acres prescribed in Art. 6, shall not apply or be in force in respect to any medical district situate wholly or in part within the Principality of Wales; but no medical district situate wholly or in part within that Principality shall be assigned to any medical officer residing more than seven miles from any part of any parish included within such district, unless the formation of such district shall have been specially sanctioned by the Poor-Law Commissioners in the same manner as is directed in Art. 8.

*Rates of Payment in Surgical and Midwifery Cases.*

Art. 10. No salary of any district medical officer, or contract made by any Board of Guardians with a district medical officer, shall include the remuneration for the operations and services of the following classes performed by such medical officer in that capacity for any out-door pauper, but such operations and services shall be paid for by the Board of Guardians according to the rules specified in this Article.

1. Amputations of Leg, Arm, Foot, or Hand . . . .	}	£ s. d.
2. The operation for Strangulated Hernia . . . .		
3. The operation of trephining for fractured skull . . . .		
4. Treatment of compound fractures of the thigh . . . .		
5. Treatment of compound fractures or compound dislocations of the leg. . . .		
6. Treatment of simple fractures or simple dislocations of the thigh or leg . . . .	}	3 0 0
7. Treatment of dislocations or Fractures of the Arm. . . .		

The above rates to include the payment

for the supply of all kinds of apparatus and splints.

Provided that in every such case the patient survives the operation not less than thirty-six hours, and that he has required and has received several attendances after the operation by the medical officer, who has performed the same.

Provided also, that except in cases of sudden accident immediately threatening life, no medical officer shall be entitled to receive such remuneration for any amputation or for the operation of trephining unless he shall before performing such amputation or operation have obtained at his own cost the advice of some Member of the Royal College of Surgeons of London, or of some Fellow or Licentiate of the Royal College of Physicians of London, and shall produce to the Board of Guardians a certificate from such Member of the Royal College of Surgeons, or such Fellow or Licentiate, stating that in his opinion it was right and proper, that such amputation or operation should be then performed.

Art. 11.—All trusses furnished by a medical officer in consequence of any contract with or direction of a Board of Guardians, shall be charged by such medical officer at the cost price, including carriage, and be paid for accordingly by such Board of Guardians.

Art. 12.—The delivery of any woman in childbirth and the subsequent medical attendance upon her by any medical officer, in that capacity, whether in or out of the workhouse, shall be paid for by the Board of Guardians in the manner specified in this and the following article; that is to say:

In cases in which any such medical officer shall be called on by order of any person legally qualified to make such order, to attend any woman in or immediately after childbirth, or shall be required, under circumstances of difficulty or danger, without any order, to visit any such woman actually receiving relief, or whom the Board of Guardians may subsequently decide to have been in a destitute condition, such medical officer shall be paid for his attendance and medicines by a sum of not less than ten shillings, nor more than twenty shillings, as the Board of Guardians may determine, regard being had to the distance from the residence of such medical officer.

Art. 13.—Provided that in any special case in which great difficulty may have occurred in the delivery, or long subsequent attendance may have been requisite, such medical officer shall receive the sum of two pounds; and if in any such case, any dispute shall arise between the board of Guardians, and such medical officer, such medical officer shall not receive the said sum until the Poor-Law Commissioners shall have signi-

fied their approval of such a payment on a report made by such medical officer, and transmitted to them through the Board of Guardians of the said Union.

*Substitutes for Medical Officers.*

Art. 14.—Every medical officer appointed, or to be appointed, in pursuance of the rules, orders, and regulations of the Poor-Law Commissioners, shall be bound to visit and attend personally the poor persons entrusted to his care, and shall be responsible for such visits and attendances, and shall so keep any weekly return prescribed by the orders of the Poor-Law Commissioners, as to show when the visit or attendance made, or given to any pauper was made, or given by any person other than himself.

Art. 15.—Every medical officer to be hereafter appointed, shall, if practicable, within twenty-one days of the time of his appointment, name to the Board of Guardians some legally qualified medical practitioner to whom application for medicines or attendance may be made in the case of his absence from home, or other hindrance to his personal attendance, and who will supply the same at the cost of such medical officer, and the name and residence of every medical practitioner so named shall be forwarded by the clerk to the Guardians to each relieving officer, and to the overseers of every parish in the Union.

*Mode of obtaining medical relief by permanent paupers.*

Art. 16.—The Board of Guardians shall, once in every six months, cause to be prepared a list of all such aged and infirm persons, and persons permanently sick or disabled, as may be actually receiving relief from such Board of Guardians, and residing within the district of each medical officer of the Union, and shall from time to time furnish to each medical officer a copy of the list aforesaid.

Art. 17.—Every person whose name shall be inserted in such list, shall receive a ticket in the following form, and shall be entitled on the exhibition of such ticket to the medical officer of his district to obtain such advice, attendance, and medicines, as his case may require, without any order from the relieving officer, overseer, or other authority.

*Form of Ticket.*

_____ UNION.	
Date _____	
Good until the _____ day of _____ 184	
Name of Pauper _____	
Residence of Pauper _____	
Name of Medical Officer _____	
Residence _____	
Usual hour at which he is at home _____	

Art. 18.—Such medical officer shall on the exhibition to him of the said ticket, and on application made on behalf of the party to whom such ticket was given, be held responsible for affording such advice, attendance, and medicines, as he may be bound to supply, in the same manner as if he had received in each case a special order from the Board of Guardians, or from any officer, to afford such advice, attendance, and medicines.

Art. 19.—Provided always that if on complaint of any medical officer it be made to appear to the Board of Guardians, that any poor person who may have been furnished with a ticket in the aforesaid form shall have wilfully applied to, or sent for the medical officer, on frivolous grounds, such poor person shall for the first time be admonished by the Board of Guardians, and on a repetition of such frivolous application, such poor person shall be deprived of his ticket, and thenceforth, until the next half-yearly list be made out, shall not be empowered, except in cases of sudden and urgent necessity, to demand advice, attendance, or medicines, from such medical officer without an order from the Board of Guardians, a relieving officer, or an overseer of some parish in the union.

*Continuance in Office of Medical Officers.*

Art. 20.—Every medical officer duly appointed in pursuance of the orders and regulations of the Poor-Law Commissioners shall, unless the period for which he is appointed, be expressly entered on the Minutes of the Guardians at the time of making such appointment, or be expressly inserted in a written contract entered into by such medical officer, and such period have been subsequently approved by the Poor-Law Commissioners, continue in office until he may die or resign, or become legally disqualified to hold such office, or be removed therefrom by the Poor-Law Commissioners.

*Explanation of terms.*

Art. 21.—Whenever the word "Union" is used in this order, it shall be taken to include not only an union of parishes formed under the provisions of the hereinbefore recited Act, but also any union of parishes incorporated or united for the relief or maintenance of the poor under any local act of Parliament.

Art. 22.—Whenever the word "Guardians" is used in this order, it shall be taken to include not only guardians appointed or entitled to act under the provisions of the said hereinbefore recited act, but also any governors, directors, managers, or acting guardians entitled to act in the ordering of relief to the poor from the poor-rates under any local Act of Parliament.

Art. 23.—Whenever the words "Board of Guardians" are used in this order, they

shall be taken to mean not only a board of guardians competent to act under the provisions of the said hereinbefore recited Act, but also such guardians, or such a number of any guardians as are competent to order relief to the poor from the poor-rates under any local Act of Parliament.

Art. 24.—Whenever the word “parish” is used in this order, it shall be taken to signify any parish, township, village, or other place separately maintaining its own poor.

Art. 25.—Whenever the word “medicines” is used in this order, it shall be taken to include all medical and surgical appliances; and whenever the words “medical attendance” are used in this order, they shall be taken to include surgical attendance.

Art. 26.—Whenever the words “medical officer” are used in this order, they shall be taken to include any person duly licensed as a medical man, who shall have contracted with any Board of Guardians for the supply of medicines, or for medical attendance.

Art. 27.—Whenever, in describing any person or party, matter or thing, the word importing the singular number or the masculine gender only is used in this order, the same shall be taken to include, and shall be applied to, several persons or parties as well as one person or party, and females as well as males, and several matters or things, as well as one matter or thing, respectively, unless there be something in the subject or context repugnant to such construction.

Art. 28.—Whenever in this order any article is referred to by its number, the article of this order bearing that number shall be taken to be signified thereby.

---

**LAST REPORT  
FROM THE  
NATIONAL VACCINE INSTITUTION.**

(Ordered by the House of Commons, to be  
printed, 8th March, 1842.)

---

*To the Right Hon. Secretary of State for  
the Home Department.*

SIR,—We feel a sincere satisfaction in being able to assure you that we have had abundant evidence, in the course of the last year, of the increasing confidence of the country in the protective power of vaccination; though this satisfaction is somewhat diminished by the frequent avowal of our correspondents of their inability to maintain a supply of genuine authentic lymph without the aid of that afforded by this national establishment.

Among other facts which prove the importance attached to the existence of this board, we may mention, that small-pox having broken out in the Orkney Islands,

immediate recourse was had to the board, and a large quantity of lymph sent thither, which appears to have arrested the progress of this horrible malady, and probably to have placed the inhabitants of those distant parts of her Majesty's dominions beyond the fear of its recurrence.

We have vaccinated, at the several stations within and in the immediate neighbourhood of the metropolis, 15,361 subjects; and have sent out to our correspondents and to the colonies, at the instance of Government, 152,668 charges of vaccine lymph.

We have, &c.

(Signed) HENRY HALFORD.

G. J. GUTHRIE.

EDWARD J. SEYMOUR, M.D.

CLEMENT HUE, M.D. Registrar.

National Vaccine Establishment,  
March, 1842.

**SUFFOCATING COUGH.**

---

*To the Editor of the Medical Gazette.*

SIR,

I BELIEVE suffocating cough has not at present any remedy proposed for it, but a smart tap on the back. This is a practice I think not so good as might be proposed or wished for, and one that I would not allow to be practised on myself, nor do I think there are many who would. If we consider a little what takes place, we must see that the constant cough during the paroxysm allows of scarcely any other action of the lungs than forcible expiration, and might thus proceed if the lungs were exhausted sufficiently to cause closure of the glottis. From these considerations, it follows that our endeavours must be directed in such a way as to prevent the exhaustion of the lungs going on. This brings me to the method I adopted, or rather invented, years ago, for the relief of this very distressing affection. It is so simple that I am surprised it has not been proposed before. My method of proceeding is, to close the patient's nostrils with my thumb and forefinger during expiration, and leaving them free during inspiration, and in a very short time the patient will be relieved from his paroxysm. I have followed this plan whenever I have had occasion to do so, and always with success. In confirmation of this practice, I think I cannot give a more illustrative case than the following:—A near and dear relative, afflicted with hemiplegia nearly thirteen years, consequent on an attack of apoplexy, of very advanced age, being rather more than 80 when she died, during the last two years of her life she was repeatedly seized with paroxysms of suffocating cough, which threatened at times to suffocate her—in fact she coughed some-

times till her face became of a bluish tint, and I have been in considerable doubts which way the balance would turn. When those paroxysms first occurred, I was not prepared with any remedy, but after a time, as her deglutition became more affected, they occurred so often, that I was in a manner obliged, if possible, to devise a remedy, and which was my method described above, and which never failed to relieve her. I think a case more in point, or one more disadvantageous, cannot well be imagined.

Yours respectfully,  
G. ROBINSON.

Feb. 11, 1842.

NORTH OF ENGLAND MEDICAL  
ASSOCIATION.

At a meeting of the council of the North of England Medical Association, held at Newcastle upon Tyne, March 16th, 1842, Dr. Headlam, President, in the Chair—

The letter of Mr. J. B. Maughan relative to an alleged breach of professional etiquette, which appeared in the MEDICAL GAZETTE of January 7, the Lancet of January 15, and the Provincial Medical and Surgical Journal of January 15, was taken into consideration, and the following resolutions adopted:—

1. That Mr. Maughan merits the approbation of the council for the gentlemanly forbearance with which he has conducted himself in this transaction.

2. That Dr. White was in error when he consented to inquire of the patient under the care of which surgeon she wished to remain.

3. That the conduct of Mr. Annandale in removing the splints and bandage from a broken limb which had been reduced by another surgeon (more especially when the immediate attendance of that surgeon was expected) was improper, and that his appropriation of the patient of another practitioner was contrary to the rules of etiquette by which professional gentlemen should be guided in their deportment towards each other.

4. That the council sincerely regret that the conduct of any of their professional brethren should have given occasion for the preceding resolutions. They earnestly hope that, in future, a better feeling will exist amongst medical men, and that similar cases will not recur.

5. That copies of these resolutions be sent to the journals in which Mr. Maughan's letter was published.

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, March 18, 1842.

J. T. R. Burroughs.—F. H. Simpson.—Joseph Vardy.—Peter Milner.—Spencer Weston.—T. M. Kendall.—R. Ransom.—D. S. Moore.—C. Chubb.—E. J. Waring.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED  
CERTIFICATES.

Thursday, March 10, 1842.

A. Catherwood, 21, Charles Square, Hoxton.—A. B. Middleton, Market Drayton, Salop.—F. Andrews, Newport, Isle of Wight.—George F. White, 8, Haymarket, London.

Thursday, March 17, 1842.

H. Hayes, Hales, Owen.—H. S. Taylor, Guildford.—E. Evans, Devonport.

NOTICES.

Dr. Watson's Lectures will be resumed next week, and concluded in the present volume.

M. Lugol's Lectures have been postponed in consequence of his having been prevented by illness from revising them. We expect to be able to give them in our next volume.

WILSON & OGILVY, 57, Skinner Street, London.

LECTURES  
ON THE  
PRINCIPLES AND PRACTICE OF  
PHYSIC,

*Delivered at King's College, London,*

BY DR. WATSON.

*Dyspepsia. Physiology of digestion.  
Symptoms of Dyspepsia: Treatment  
and prevention, dietetic and medicinal.*

It is my intention to appropriate this evening's lecture to a cursory account of *dyspepsia*: by which I mean some evident derangement in the natural process of digesting and assimilating our food; and more especially, a faulty performance of the functions of the *stomach*. Indigestion is the prevailing malady of civilized life. We are more often consulted about the disorders that belong to eating and drinking, than perhaps about any others: and I know of no medical topic concerning which there is afloat, both within and beyond the profession, so much ignorant dogmatism and quackery.

Cullen, in his definition of *dyspepsia*, enumerates the various symptoms, by the occurrence of more or fewer of which, that complaint is most commonly manifested. "Anorexia, nausea, vomitus, inflatio, ructus, rumination, cardialgia, gastrodynia:—pauciora saltem vel plura horum simul concurrentia, plerumque cum alvo adstricta, et sine alio vel ventriculi ipsius, vel aliarum partium, morbo."

The variety in the actual presence and combinations of these symptoms is very great: and any attempt to give a perfect or complete history of *dyspepsia* in these lectures is quite out of the question. But I will endeavour to draw such a general outline of the disorder as may assist and direct your observation of it hereafter.

I shall first take a brief view of the *pathology* of indigestion, so far as it is under-

stood: and to make this intelligible, it will be necessary to interweave something of the *physiology* of the subject. To these preliminary considerations, I shall add a short comment upon the several symptoms of *dyspepsia*, enumerated in Cullen's definition: and lastly, I shall state what I know respecting the means of curing, and of preventing, this familiar disorder.

The conditions of healthy digestion are these: that the food should be masticated, mixed with saliva, and swallowed into the stomach: that in the stomach it should be reduced to a semi-fluid consistence, and converted into a uniform pulp, called *chyme*: that the *chyme* should be transmitted through the pylorus into the duodenum, and there mixed with the bile, the pancreatic secretion, and the intestinal mucus; in consequence, as it would seem, of which admixture, the whole is separated into two parts; viz. the *chyle* or the nutritive portion of the food, now in a fit state to be taken up by the lacteals which open upon the mucous surface of the intestines, and to be carried by them into the blood; and the excrementitious portion, which at length is conveyed out of the body.

The food is dissolved and transformed, in the stomach, by the chemical agency of the *gastric juice*. This is a secretion peculiar to the stomach. All that need be stated of it here—almost all indeed that is known—is, 1st, that it oozes forth in minute drops from the mucous surface; but only when food (or some solid substance), is present in the stomach: and 2ndly, that it is always *acid*. It appears to owe its solvent power to a special principle, which chemists have named *pepsin*.

The food, having arrived in the stomach, is moved about, by a sort of churning or revolving movement, and mixed with the gastric juice, and gradually changed into *chyme*: which also is acid. Finally, the *chyme* is propelled by degrees into the duodenum by the pressure of the transverse

band of muscular fibres which embraces the pyloric extremity of the stomach. The time in which the whole operation is completed varies from two to four or five hours.

Liquids introduced into the stomach disappear much more speedily; either by direct absorption, or through the pylorus.

All this we know, not from mere speculation on the anatomy and uses of the organ, but from actual observation. An American physician had, for several months in succession, the curious privilege of looking, whenever he pleased, into a healthy human stomach, and of watching its condition, its movements, and its contents, during the process of digestion. A young Canadian had a portion of the skin, muscles, and ribs, of the left side of the body blown away in a gun-shot wound, which laid open the stomach also. He recovered from this frightful injury with a permanent aperture in the side, communicating directly with the stomach. Through this loop-hole Dr. Beaumont was allowed to introduce various articles of food; and to withdraw from time to time the gastric secretions; and the aliment, in the different stages of its digestion. He has published a very interesting account of these experiments, which have set at rest some points in the physiology of the stomach that were previously uncertain. I shall embody his deductions in what I have farther to say on the subject.

In order that digestion may be perfect and easy, it is requisite that the food should be in a state of minute division. This object is attained by *mastication*. A weak dyspeptic stomach acts slowly, or not at all, on solid lumps and tough masses of food. The delayed morsels undergo spontaneous changes, promoted by the mere warmth and moisture of the stomach: gases are extricated: acids are formed: perhaps the half-digested mass is at length expelled by vomiting; or it passes undissolved into the duodenum, and becomes a source of irritation and disturbance during the whole of its journey through the intestines. Here then we have one common cause of dyspepsia; and an easy and obvious preventive. Dyspeptic persons should not eat in a hurry, as busy men, and studious and solitary men, are apt to eat. They are to be cautioned against *bolting* their food: it must be well ground in the mill that nature has provided for that purpose. I am not at all sure that the increased longevity of modern generations is not, in some degree, attributable to the capability of chewing their food which the skill of the dentist prolongs to persons far advanced in life.

There are certain things upon which the gastric juice has no power. The green colouring matter of certain vegetables; the husks of seeds; the rinds of many fruits. You may perhaps have observed that dried

currants, and the pips of apples, swallowed entire, reappear, unchanged, among the egesta. Whatever passes the stomach untouched by the gastric liquor, passes undissolved through the whole of the alimentary canal; provoking disorder sometimes in its transit; forming sometimes a nucleus for intestinal concretions. These substances are therefore unfit for a weak stomach. When the digestive powers are active, and the bowels slow, they may perhaps occasionally be even useful. Thus brown bread—*i. e.* the indigestible bran, or tegument of the kernel of wheat—stimulates the peristaltic motions of the intestines, and averts, in certain persons, the necessity of more direct purgatives. Unbruised mustard seed, once so much in vogue, owed whatever virtue it possessed to this principle. But if these intractable substances fail to excite the proper action of the bowels, they are apt to accumulate, and to lay the foundation of serious disease.

Indigestible matters, to which the pylorus refuses a passage, may remain in the stomach, and disturb its functions, for days, or even sometimes for weeks, together. If we could ascertain their presence, an emetic would be the remedy. And sooner or later vomiting is set up, and the offending substance expelled. I lately saw a mass of hard curd—a small cream cheese in respect to consistence—which was thrown up after several days of severe gastric pain and disorder. The relief was immediate and complete. The patient had been taking large quantities of cream with his tea and coffee. In another person, a similar fit of indigestion terminated in the ejection of a mass of snuff. This is no unusual source of derangement of the stomach among those who use lavishly that nasty luxury.

The essential change which the chyme undergoes after leaving the stomach, appears to consist in its separation into two parts: namely, into chyle, which is taken up by the lacteals; and into excrement, which is discharged from the body. Any undissolved portions of the food become attached to this last part. We do not know exactly what is the function or agency of the pancreatic liquor; but with regard to the bile our knowledge is somewhat more definite. The acid developed in the stomach combines in the duodenum with the alkali of the bile, and is more or less neutralized. Dr. Prout conjectures that in a healthy state of the organs it is entirely neutralized. Bile is, moreover, the natural stimulus of the intestines: when its secretion is stopped, or its passage into the duodenum prevented, digestion and assimilation may go on, but the bowels are usually sluggish. The hepatic secretion has doubtless other important uses; but with these we are not at present concerned. It is pretty evident that the state of the biliary

functions can have no direct influence in the production of mere dyspepsia. When the bile is deficient in quantity, or vitiated in quality, the *nutrition* may be thereby affected. And when the functions of the stomach and the functions of the liver are both disordered, it *may be* that the former organ sympathizes indirectly with the morbid state of the latter; or it *may be* that one and the same cause operates in producing the derangement of both organs.

Let us now review the symptoms of dyspepsia which are mentioned in Cullen's definition. The first of these is *anorexia*: want of the natural appetite. Sometimes this is almost the only symptom observable. The patient is warned, by loss of appetite, not to take too much food; he refrains instinctively from certain kinds of food; or he feels perhaps absolute repugnance and disgust at the very thought of eating. Various have been the speculations respecting the immediate cause of hunger. It has been ascribed to the action of the gastric juice upon the surface of the empty stomach. But during health, the gastric juice is never present in an empty stomach. Neither can the appetite depend upon contraction of the muscular fibres of the stomach; for the empty stomach, during health, is always contracted upon itself. No doubt the sensation of hunger, like all other sensations, arises from some particular condition of the *nerves* of the part. It returns periodically, acknowledging in this respect the influence of habit. It is sensibly affected by agencies which operate upon and through the nervous system. The receipt of a piece of bad news will destroy, in a moment, the keenest appetite.

Sometimes there is no anorexia. The appetite may even be morbidly craving and ravenous; or capricious and uncertain.

When defect of appetite is the only symptom, it may be remedied, often, by the employment of bitters, or of the mineral acids, taken twice or thrice daily, for some time together. It would be out of place for me to speak in detail of particular medicines of this kind: it is enough if I indicate quina, columbo, gentian, quassia; the dilute sulphuric and nitric acids; or a mixture of the nitric and muriatic.

*Nausea—vomitus.*—These are, in some instances, the most distressing results and signs of the dyspepsia. Sometimes nausea comes on soon after the food is swallowed. Sometimes there is no nausea; but after the lapse of a certain period, an hour or two generally, the food is rejected by vomiting. The matters thus thrown up are most frequently sour. Not seldom they are mixed also with bile, especially if the retching has been violent, or long continued; and then the patient is apt to ascribe the whole of his complaint to "an overflow of bile,"

although in fact the secretions of the liver have nothing whatever to do with it; the appearance of bile in the fluids ejected from the stomach proceeding from an inverted action of the duodenum. The effort of vomiting, however induced, will, if often repeated, be attended with the expulsion of yellow bile. I have more than once referred you, for an illustration of this fact, to the phenomena of sea-sickness. The fallacy I now point out has been one cause of the notion that is prevalent among patients, and the public—and not unfrequently perhaps among practitioners—that dyspepsia very commonly depends upon a disordered state of the biliary organs.

The vomiting which occurs in dyspepsia is often connected with a morbid irritability of the stomach; and it is sometimes a very troublesome symptom to treat. The carbonic acid has certainly a marked effect in allaying it in many cases. We give it, as you know, in the effervescing saline draught, made with the carbonate of potash, or soda, and lemon-juice. Sometimes the mineral acids answer better. Sometimes, on the other hand, alkalies—the liquor potassæ, for example—or lime water, are more effectual. In these latter cases we may presume that there is a morbid acidity of the stomach. Small doses of opium are sometimes successful when other means fail. Opiates thrown into the rectum—opium plasters to the epigastrium—blisters to the same part: these are measures which you will sometimes have to try one after another. There are two special remedies which have been greatly extolled for their virtue in abating sickness: the hydrocyanic acid is one of them; creasote is the other. The hydrocyanic acid I have found exceedingly useful in obstinate cases. It may be given alone—or mixed with the effervescing draught—or combined with a few grains of the sesquicarbonate of soda. The creasote has disappointed me oftener than it has answered my hopes from it. Yet it has a decided influence in checking some forms of nausea; and it is the more likely to succeed, in proportion as the condition of the stomach is remote from inflammation.

But after all, the grand principle on which to treat chronic vomiting—not dependant upon disease in other parts, as the head, the kidney, or the uterus—is that laid down by Dr. William Hunter; of reducing the *quantity* of food to that amount, whatever it may be, which the stomach is able and willing to retain, and of making its *quality* as bland and nutritious as possible. The most satisfactory case which I have had to treat upon this principle occurred some years ago, in the person of one of my hospital patients. She was brought out of Kent by her father. She had been under the care of several medical men, one of whom had been a pupil

of the hospital, and recommended her as a proper patient for admission there. Her age was sixteen. She and her father both agreed in the same story; viz. that she constantly vomited her meals; the food generally coming up again immediately after it was swallowed, and never remaining longer in the stomach than ten minutes. The vomiting was described as being easy; and was neither preceded nor accompanied by nausea.

She had been ill for four years: ever since a severe attack of scarlet fever. At first she vomited her meals now and then—three or four times a week—but the vomiting gradually became more and more frequent; and at the time of her admission she had vomited after *every* meal, for three months in succession. She had grown considerably in the four years; and was tolerably plump; and looked healthy; and the catamenia had begun to appear, though scanty, in the same period: but they had been altogether suspended for a year.

It was clear that a good deal of her food must have remained: and, bearing William Hunter's case in mind, I directed that she should have a very small quantity of roast meat for dinner, and a coffee cup of milk occasionally during the day; and no other food. I prescribed also some pills, consisting of aloes and soap, to act moderately on the bowels. I expected to have been obliged still farther to limit her food: but she never vomited again, from that time. This distressful and protracted disorder, after long and fruitless treatment previously, yielded thus at once and easily to very simple means.

*Inflation—ructus.* Flatulence, and belching. The gas that produces these symptoms is sometimes extricated from undigested food detained in the stomach, and in a state of fermentation: sometimes secreted, apparently, by the stomach itself; for the flatulence comes on when the stomach is empty of food. It is apt to arise, in dyspeptic persons, if a meal happens to be delayed beyond the accustomed hour. Patients complain grievously of these symptoms, and accuse the "wind in their stomach" as being at once the essence and the cause of all their complaints. They ask for medicines to get rid of the wind; and its escape may indeed be promoted by warm aromatics, and carminatives, as they are called: the relief thus afforded to the distended stomach being so sudden and for the time so complete, that the sufferer ascribes to the medicine *vis carminis*, the power of a charm. One of the most effectual and popular of these carminatives is peppermint water. A due regulation of the periods for taking food will often suffice to obviate the flatulence that belongs to emptiness. That which follows eating may, in many cases, be prevented, by swallowing, immediately before

the meal, five or six grains of the extract of rhubarb, with or without a grain of cayenne pepper. If the ascending wind brings into the throat and mouth a portion of the solid contents of the stomach, the patient is said to *ruminate*. The regurgitated matters are often intensely acid; and then an alkali may remedy the flatulence; a tea spoonful of *sal volatile*, for example.

Indigestion is, in many instances, attended with scarcely any pain; while in others the pain is very tormenting. Cullen speaks of it under the terms *cardialgia*; and *gastrodynia*. Cardialgia is that less violent and more permanent uneasiness which in popular language is called *heart-burn*. Gastrodynia is that more severe, and usually more transient pain, which is commonly denominated *spasm* or *cramp* of the stomach.

Dr. Abercromby has some useful practical observations in respect to pain of the stomach. He speaks of it as occurring under four different forms; and I am able to bear witness to the reality of the distinctions that he has drawn. In the first place, some persons suffer pain, occasionally, when the stomach is empty, even when there is no flatulence; and they are comforted and relieved by taking food. It is reasonable to suppose that this kind of pain depends upon some degree of acrimony of the fluids of the stomach itself. It is often removed at once by alkalies, or absorbent medicines. A tea spoonful of the aromatic spirit of ammonia, or a table spoonful of the liquid magnesia, in a wine glass of camphor julep, will still the whole uneasiness sometimes in a moment, as if by magic.

A second form of pain in the stomach is when it occurs *immediately* after taking food, and continues during the whole process of digestion, or until vomiting ensues, which gives instant ease. In such cases we have reason to suspect the existence of chronic inflammation, or of some undue sensibility of the mucous membrane of the stomach. The suitable remedies are such as I spoke of in the last lecture. I might have mentioned a form of medicine which Dr. James Johnson has found especially serviceable against this morbid sensibility; I mean the nitrate of silver, in small doses.

In a third species of painful disorder of the stomach the pain does not begin till from two to four hours after a meal, but continues for several hours. This is a very common form of complaint. Dr. Abercromby is of opinion that the pain is seated in the duodenum, and connected with inflammatory action, or with morbid sensitiveness of the mucous lining of that bowel. He says it is frequently accompanied by pain and tenderness of the right hypochondrium; and that the liver is often blamed when it really is not in fault. This last remark I

well believe; but I am not so easily persuaded that the pain is duodenal. I believe it depends upon acidity in the primæ viæ. It has been ascertained, by several chemists, that the acid which is present in the gastric juice is the muriatic. Dr. Prout holds that the source of this muriatic acid is the common salt which exists in the blood, and that the decomposition of this salt is owing to the immediate agency of some modification of electricity; and he conceives that the principal digestive organs represent a kind of galvanic apparatus, of which the mucous membrane of the stomach and intestinal canal may be considered as the acid or positive pole, while the hepatic system is the alkaline or negative pole. However this may be, it is certain that the muriatic acid contained in the stomach is often in excess: other acids are also found there—the acetic, and more especially the lactic; and when the food, now converted into chyme, passes into the duodenum, the remaining superfluous acid teases the stomach. I think this explanation of the cause of the pain is a more probable one than Dr. Abercromby's, because you may generally mitigate or remove the pain by introducing an alkali into the stomach, whereby the acid is neutralized: even the swallowing a cup of warm tea, by which the acid is diluted or washed away, often stops the pain. And I have, in numerous instances, succeeded in *preventing* the recurrence of this pain by directing the patient to take a small quantity of alkali, in some aromatic water, immediately after his dinner. According to Dr. Abercromby's theory the pain ought not to be so immediately allayed by these remedies; and, since the food is gradually propelled into the duodenum as it is digested, the pain should begin, I think (supposing him right), earlier than it does. Dr. Abercromby has found nothing of more general utility in these cases than the sulphate of iron, combined with one grain of aloes, and five grains of aromatic powder, taken three times a day. He praises lime-water also, and small opiates, and a combination of bismuth and rhubarb. What its *modus operandi* is I know not, but I am sure that bismuth is a very effectual remedy for some kinds of gastric distress.

Pain in the stomach occurs in a fourth form, coming on at uncertain intervals in most violent paroxysms, and properly called *gastrodynia*. It is often accompanied by a sensation of distension, much anxiety, and extreme restlessness. In females it is frequently combined with hysterical symptoms. This form Dr. Abercromby supposes to depend upon over distension of the stomach; and it may be so: certainly great quantities of air are sometimes extricated; and the pain is not confined to the stomach, but

shoots through to the back and between the shoulders. I suspect that the pain is sometimes neuralgic. It is often very intractable: occasionally it yields to carminatives. Dr. Abercromby states that he has observed the most effectual relief in such cases to have been obtained from exciting a brisk action of the bowels by means of a strong purgative enema. He makes this practical remark, which is worth attending to. From the facility with which such affections often yield to the remedy first mentioned, it appears not improbable that the pain may be sometimes situated in the arch of the colon. Wherever it may be situated, I know that it is frequently removed by a mustard poultice laid upon the epigastrium. Opium also is of eminent use in many of these cases; and cordials: but I have seen more rapid and decided relief afforded by the prussic acid than by any thing else; and the cure so wrought is often permanent. It does not bring ease in all cases, nor is it a medicine that is any particular favourite of mine, yet its good effect is in some instances so striking, that if this were its only virtue I should esteem the hydrocyanic acid a most valuable remedy.

You will meet sometimes with what is called *spasm* of the stomach (and I suppose it is such) in gouty people; who are then said to have gout in the stomach. The pain comes on in sudden and severe paroxysms; and is removable in general by laudanum and stimulants, brandy, for example; or by the mustard poultice. On these cases, however, we look with jealousy and apprehension. In some instances the attack is really inflammatory, and would then be aggravated by a stimulant treatment.

There is yet another modification of uneasiness and disorder of the stomach, of which the distinguishing characteristic is the vomiting, or rather the eructation of a thin watery liquid, sometimes sourish, but usually insipid and tasteless, and often described by the patients themselves as being cold. This is what Cullen calls *pyrosis*, the *water-brash*. It is a disorder much more frequent in the lower ranks of society than in others. It is particularly common in Scotland, and is there ascribed to the large employment of farinaceous substances as food, and especially of oatmeal. But it is said to be still more common in Lapland. Dr. Cullen, who saw a great deal of it, says that its paroxysms “usually come on in the morning and forenoon, when the stomach is empty. The first symptom of it is a pain at the pit of the stomach, with a sense of constriction, as if the stomach was drawn towards the back. The pain is increased by raising the body into an erect posture, and therefore the body is bended forward. The pain is often very severe; and after continuing for some time, it brings on an eructation of a thin

watery fluid in considerable quantity." Such is Cullen's description of pyrosis. He states that the complaint often occurs without other symptoms of dyspepsia; but this is not consistent with the experience of subsequent observers. It is a symptom sometimes of organic disease of the stomach. In one remarkable case of pyrosis which I saw, and in which not less than three pints of this thin tasteless liquid was brought up every day, the stomach, after death, was found to all appearance healthy; but it had been pressed upon by an enormous liver. I mention these facts that you may not suppose pyrosis to be always, as Cullen has described it, a substantive and idiopathic malady.

When pyrosis is not caused by organic disease in the stomach or in the liver, it will yield in general to opium, and especially to opium in combination with astringents. The *pulvis kino compositus* of the pharmacopœia is an admirable remedy for it. But we often have to contend with this difficulty, that the bowels, in cases of pyrosis, are generally confined, and that the opium tends to aggravate this unnatural condition; so that it becomes necessary to administer some aperient daily while the kino and opium are given: castor oil, or confection of senna, or cathartic extract.

*Costiveness* is, in fact, a very frequent concomitant of dyspepsia, as Cullen's definition affirms (*plerumque cum alvo adstrictâ*). And this sluggish state of the bowels often aggravates if it does not produce the dyspepsia. At any rate the defective powers and uneasy sensations of the stomach are rectified, in many instances, by measures which promote the regular and healthy evacuation of the intestines. Without professing to go into detail in this matter, I may state that, in our remedial attempts, we should imitate, as much as we can, the processes of nature. The mixed contents of the small intestines furnish the natural stimulus of their peristaltic movements; and the excrement excites the larger bowels. When this natural stimulus is insufficient, the want may be supplied by some substance which is involved in the food, and accompanies it in its progress—as the bran of brown bread, already mentioned, or a few grains of rhubarb or of aloes swallowed immediately before dinner. In adjusting the proper quantity of the drug the patient must assist the physician. It should be just so much as suffices to effect what nature neglects to do, and no more. With some persons an aperient pill acts more comfortably and opportunely if taken at bed time. Sometimes diarrhoea is associated with indigestion. This is usually connected with an excess of acid in the *primæ viæ*. The principle of treatment in such cases is obvious.

There are innumerable sympathies of distant parts with a dyspeptic stomach, in respect to which I can do little more than barely enumerate a few. Thus indigestion is often accompanied by pain in the head, with some confusion of thought; or at all events, with a loss of mental energy and alertness. Together with the violent headache there is frequently nausea and vomiting; and the complaint is popularly known by the name of the *sick headache*; or, in the fashionable jargon of the day, as a *bilious headache*. I must refer you to a paper of Dr. Fothergill's in the 6th volume of the *Medical Observations and Inquiries* for a very good account of this troublesome complication.

I shall hereafter have a good deal to say respecting certain morbid conditions of the urine, which take their rise sometimes from faulty digestion in the stomach, sometimes from faulty assimilation of the digested aliment in the more advanced stages of the process of nutrition. These conditions of the urine, indicating grave derangements of the whole system, furnish the characters and the names of several distinct maladies.

I told you, in a former lecture, that certain affections of the viscera of the thorax are liable to be produced by mere indigestion. Palpitations of the heart, irregularities of the pulse, fits of asthma, are no uncommon accompaniments of a disordered stomach. This is partly to be ascribed to that reflex sympathy between the parts concerned, which I have so frequently mentioned; partly to the effect of flatulence, which, by resisting the descent of the diaphragm, impedes the free working of the lungs and of the heart. I told you, at the same time, that these symptoms torment many persons with the belief that they spring from organic disease. This notion is particularly apt to infect the minds of medical students. I suppose most teachers in our profession partake of that sort of experience which Dr. James Gregory, of Edinburgh, used to speak of in his lectures. He said that scarcely a winter passed over in which several of his pupils did not apply to him on account of palpitations, supposed by them to depend upon structural disease of the heart: and in no single instance were their apprehensions well founded. They were all cases of mere dyspepsia and hypochondriasis.

Dyspepsia is often connected with phthisis, with leucorrhœa, with amenorrhœa and chlorosis: and some persons imagine that these diseases are *caused* by the dyspepsia. Indigestion may lead indirectly to the development of consumption, by producing debility; but the truer view of the matter seems to be that the dyspepsia is a consequence, rather than an exciting cause, of these complaints. When,

for instance, leucorrhœa is cured by topical astringents, as it often may be, the indigestion is often cured too.

One of the worst occasional concomitants of dyspepsia is that peculiar state of the mind to which I just now alluded under the term *hypochondriasis*. This is, in truth, a species of insanity: but it is so often connected with disorder of the digestive organs, that Cullen, whose descriptions of disease are admirably clear and true, however faulty many of his theories may be, defines hypochondriasis to be "*Dyspepsia—cum languore, mæstitiâ, et metu, ex causis non æquis.*" In the following short paragraph he completes the picture. "In certain persons there is a state of mind distinguished by the concurrence of the following circumstances. A languor, listlessness, or want of resolution and activity with respect to all undertakings: a disposition to seriousness, sadness, and timidity: as to all future events, an apprehension of the worst or most unhappy state of them: and therefore, often upon slight grounds, an apprehension of great evil. Such persons are particularly attentive to the state of their own health, to every the smallest change of feeling in their bodies: and from any unusual feeling perhaps of the slightest kind, they apprehend great danger, and even death itself. In respect to all these feelings and apprehensions, there is commonly the most obstinate belief and persuasion."

Now when the attention of the hypochondriac is thus morbidly fixed upon the states and the sensations of his digestive organs (as it is very apt to be) the patient becomes a plague to his physicians as well as to himself.

There are a few simple rules which ought always to be kept in mind in our *treatment* of dyspepsia; although we can seldom enforce them, as they ought to be enforced, upon our patients. What patients want, in general, is some medicine that will relieve them from their discomfort and uneasy feelings, and allow them, at the same time, to go on in the indulgence of those habits which have generated the discomfort. And such remedies have not yet been discovered.

One great and indispensable principle in the treatment of indigestion, is that of restricting the *quantity* of food taken at any one time. The gastric juice is probably secreted in a tolerably uniform quantity. The muscular contractions of the stomach must needs be impaired or impeded by much distension of that organ. For both these reasons the quantity of food introduced into the stomach should be kept within the limits of its capacity and powers. The great good which the late Mr. Abernethy unquestionably did to a host of dyspeptic patients, was owing much more, I am persuaded, to the rules of

diet, and the restrictions as to quantity, which he laid down, than to his eternal blue pill.

Again, as Dr. Abercromby has well remarked, and as Dr. Beaumont actually saw, various articles of food are soluble in the stomach with various degrees of readiness. Therefore, when the digestion is liable to be easily impaired, it is of great importance, not only to refrain from those substances which are known to be soluble with difficulty, but also to avoid mixing together in the stomach different substances which are of different degrees of solubility. Hence there are two reasons why it is salutary to dine off one dish. 1st, Because we avoid the injurious admixture just adverted to; and 2dly, because we escape that appetite and desire to eat too large a *quantity*, which is provoked by new and various flavours.

And another very important principle, greatly insisted on by Mr. Abernethy, is, that the stomach should have *time* to perform one task before another is imposed upon it. He always made his patients (at least he always strongly exhorted them) to interpose not less than six hours between one meal and another. Allowing from three to five hours for the digestion of a meal, and one hour over for the stomach to rest in, Mr. Abernethy's rule seems as much founded in reason as it is justified by experience. But we preach in vain on these topics. Mr. Abernethy was in the habit of saying that no person could be persuaded to pay due attention to his digestive organs, till death, or the dread of death, was staring him in the face. I have now in my mind a family consisting of a mother and three grown-up daughters, who are continually ailing and valetudinary. They profess to have great respect for my professional advice: yet I never can induce them to think that their plan of eating is a bad one. They are not early risers. They get to breakfast about half after ten, or eleven. At two they think it absolutely necessary to eat luncheon, which consists of a mutton chop, or some hashed meat, with vegetables. At six they dine: and at eight they drink tea: and then they eat no more till the next breakfast. And this is just a picture of the habits of scores of families. They huddle all their food into the stomach, at four periods, within seven or eight hours; and leave it idle for sixteen or seventeen.

Dyspeptic patients are very importunate to know *what* they may eat, and (more so still) *what* they may drink. It is of course impossible to lay down any general rules which will suit every case. The stomach has its idiosyncrasies. I remember seeing a publication, some years ago, one section of which had this startling title, "*Cases of Poisoning by a Mutton Chop.*" Dr. Prout knew a person who could not eat mutton in

any form. He was thought to be whimsical, and mutton was frequently served up to him under some other guise, without his knowing it: but it invariably caused violent vomiting and diarrhoea. Yet, for the average of stomachs, mutton is probably the most digestible of all meats. And for the average of stomachs some useful general directions may doubtless be given.

In fevers and inflammatory disorders, experience has taught us to forbid or restrict the use of flesh meat on account of its stimulating qualities. And when the stomach itself is affected with chronic inflammation, or with morbid sensibility, a diet restricted to farinaceous substances, and milk, is sometimes attended with the happiest consequences. I suspect that a false analogy has led some into the mistake of supposing that animal food ought to be refrained from, or taken in a limited proportion, in merely dyspeptic complaints. Animal food is easier of digestion, in the human stomach, than vegetable food. It is nearer, in its composition, to the textures into which it is to be incorporated by assimilation. There is less of "conversion" requisite. Indeed we may look upon the appropriation of vegetable matter, by granivorous and graminivorous animals, as one stage of the process by which such vegetable matter is prepared for the sustentation of carnivorous animals: even as one great end of vegetable life seems to be that of generating or concocting matter for the nutrition of the former class, out of inorganic materials, not fitted for that purpose: A more elaborate digesting apparatus is provided for the vegetable eaters. Man, indeed, is omnivorous. But his organs of digestion are more like those of the carnivorous than of the granivorous races. And it is notorious that vegetable food, when the stomach is weak, is followed by more flatulence, that is, is digested with more tardiness and difficulty, than animal food. Nevertheless, a mixture of the two, of well-roasted or boiled flesh or fowl, with a moderate portion of thoroughly cooked vegetables, is better suited, in my opinion, for a feeble stomach, than a rigid adhesion to either kind of aliment singly. Each of the four great classes of alimentary principles specified by Dr. Prout should be represented; the aqueous, the saccharine, the albuminous, and the oleaginous. All meats that have been hardened by culinary art, or by condiments, should be avoided by him, who, as the vulgar express it, has "a bad digester;" all cured meats I mean—ham, tongue, sausages, and so forth. Mutton is thought to be more readily digestible than beef. Pork, its lean part at least, is much less so than either. All raw vegetables also must be eschewed; salads, cucumbers, pickles. But if we press our prohibitions much more strictly than this, we incur the

risk of fixing the patient's attention too curiously upon his diet, and upon the sensations of his stomach; and of rendering him hypochondriacally alive to the miserable subject of his feeding.

Again, you will be continually asked whether you recommend malt liquor or wine, wine or brandy and water, white wine or port, sherry or madeira. Now it would be very easy to propound some positive rules in this matter, but it would not be so easy to vindicate them. Some allowance must be made, no doubt, for custom. I believe, however, that most dyspeptic persons would be better without any of these drinks. But it is very difficult to persuade them that the habitual use of strong liquors in small quantities can have any injurious effects. "It is not easy (says Cullen) to engage men to break in upon established habits, or to renounce the pursuits of pleasure; and particularly to persuade men that those practices are truly hurtful, which they have often practised with seeming impunity." They are too ready to believe that it is unsafe to abandon their accustomed indulgence. A friend of mine, who visited, some years since, many of the American prisons, tells me that the health of even the most inveterate spirit-drinkers improves, instead of suffering, upon the sudden and total abstinence from spirits, which the regulations of those prisons enforce. There certainly are cases in which the digestion seems to be helped by a moderate quantity of wine, or beer, or spirits; yet no one can say before hand—at least I cannot—which of them is to be preferred. Upon these points patients should interrogate their own sensations and experience, instead of seeking the oracular counsel of a physician. Drinks which are followed by evident disturbance and discomfort are manifestly unfit. And even when a favourable effect, for the time, appears to be produced, there is always a risk of ultimate detriment to the powers of the stomach from this habitual excitement.

There are states of mind, and habits of life, which, having no direct relation to the organs of digestion, yet exercise a material influence over their functions. Mental distress; mental solicitude; mental toil; over much study; want of exercise: these are all prolific sources of dyspepsia. Sedentary habits, when their injurious effects are known, may be altered: excessive intellectual labour may be abandoned: but it is seldom that we can minister to a wounded or an anxious spirit. Our task is hardest of all when the patient's anxiety relates to his own complaints; when he is morbidly engrossed by his bodily feelings, and despondent about his recovery. The management of the mind of a hypochondriac is peculiarly nice and difficult. It will not do to treat him as if his ailments

were imaginary. He disbelieves you, contemns your judgment, and deserts you: to be fleeced perhaps by some villainous quack. You must hear what he has to say; shew an interest in his case; and prescribe for him: assuring him that you understand his malady, that it is curable, and that he will be cured provided he follows your directions. If you can succeed in gaining his confidence, and in persuading him of this, the battle is half won. To tell such a person, however, not to think of his grievances would be worse than useless. The very effort to drive a subject from our thoughts fixes it there the more surely. But you must endeavour to turn his attention to other things; and to awaken in him some new interest. Prescribe *change*: change of air; change of place and of scenery; change of society. Get him to *travel* in search of health; and the chances are in favour of his finding it. A tour, in fine weather, and through a pleasant country, combines almost all the ingredients which are, separately even, desirable: the withdrawal of the mind from its ordinary pursuits and cares; the diversion of the attention from one's self, by new and varied objects; exercise, carried on in the open air; a holiday from intellectual toil. Six weeks among the mountains of Switzerland, or upon the rivers of Germany, will often do more towards restoring a dyspeptic hypochondriac than a twelvemonth's regimen and physicking at home.

With these disjointed hints, gentlemen, I must request you to be satisfied in respect to the principles upon which dyspepsia—and the hypochondriasis, which is in general so closely linked with dyspepsia—are to be managed. A full discussion of these subjects in detail would furnish matter for several lectures.

## ON ARTIFICIAL CLIMATES,

FOR THE RESTORATION AND PRESERVATION  
OF HEALTH: TO BE CONSIDERED UNDER  
TWO HEADS.

I. *The atmospheric treatment of the lungs.*

II. *The atmospheric treatment of the lungs and skin.*

BY JULIUS JEFFREYS, F.R.S., &c.

[Continued from p. 974.\*]

*The atmospheric treatment of chronic  
diseases of the chest.*

OMITTING, with a view to brevity, an examination of the various agents which

give that influence to the air which constitutes a climate, I shall confine myself to the action of the constituents which are most important in the treatment of chronic affections of the chest, and at the same time under the control of art. These are, first, air, in which term I would comprehend the three gases—nitrogen, oxygen, and carbonic acid, in their natural proportions of about 79 of the first, 21 of the second, and one-tenth part of the last. The steadiness with which this proportion is maintained may assure us that it is that best suited for health, and we have no evidence that any other would be better for the lungs in a diseased state. Neither would it be easy to maintain for any length of time a different proportion of these elements. They may, then, for our present purpose, be treated as one. Secondly, of the imponderables which are constituents in the atmosphere, namely, heat, light, and electricity, in this place we have to deal with the first only. Thirdly, of the various terrestrial impregnations which are much concerned in giving a character to climate, we are chiefly interested in commanding the presence of a due quantity of the vapour of water, and in the exclusion of most of the others.

Air, (meaning thereby the three gases), heat, and vapour, are then the materials, by varying the proportions of which we may hope to form artificial atmospheres suited to chronic diseases of the chest.

Limiting my present remarks to the influence of what may be termed the three staple constituents of an artificial atmosphere for the lungs, namely, air (that is, the natural gaseous mixture), warmth, and moisture, it will be convenient to premise a few remarks upon the more important varieties of atmosphere, which are produced by combinations of these elements in different proportions.

We may assume a bland or balmy air to be just such a mixture as shall produce no excitement, whether pleasant or painful, but is soothing to the animal frame throughout. This may be called an atmosphere *à par*; and if the same proportions of the constituents produced in all persons the same feeling, we might ascertain to a certainty what constituted a perfect atmosphere. As it is, we must rest satisfied with the know-

---

\* In the last paper, p. 970 of the GAZETTE, the active, "overlying," was misprinted for the neuter participle, "overlying."

ledge that there is some average proportion which forms an air of the character which may be termed balmy to the generality of mankind. This, then, we may call an air at par; and although the qualities of the infinitely various mixtures run into each other, so that no line of demarcation could be drawn, we may discern six sorts of air, the characters of which are strongly marked, according as the elements vary either way, from the balmy state or that at par.

We have then to deal with, first, air having both its heat and moisture below par; that is, cold and dry air. Secondly, air having its heat below and its moisture at par; and this we call simply cold air. Thirdly, air with the heat below, and the moisture above; or cold and damp air. Fourthly, air with its heat above, and moisture below; or hot and dry air. Fifthly, with the heat above, and the moisture at par; this we recognize as simply warm air. Sixthly, with both these elements above par; or warm and moist air. This may appear giving needless formality to familiar conditions of the air; but it is not so. To the want of some classification we may trace many vague notions and actions prevalent in society with reference to atmospheric influences upon the health.

With respect to the *actual quantity* of the elements present, every one who has attended to the branch of physics which comprises this question, will bear in mind that the same absolute quantity of moisture may exist in a very damp and a very dry air; in which case the former air must be cold, and the latter hot. It is the *relative* quantities with which we are concerned, as those which exercise an influence upon the human frame. I have sometimes ascended from a deep valley in the Himalayas, where the atmosphere was hot, and manifested by the hygrometer considerable dryness. In a rapid ascent the change produced in the character of the same air, by a change only of the thermometric condition, was striking to the feelings. It by degrees acquired, at a certain height, a balmy feeling which was delightful. At a greater height it became bracing; then raw; and at a greater height still damp and chilly, and peculiarly unpleasant to respire. That it was air of the same proportional composition as that in the valley I could

not doubt, from the fact that a breeze of fresh air blew up the mountain-side during the whole ascent. When the ascent has been great, and nearly continuous, these changes have been very marked and steady; and they must have been noticed by every traveller, in such regions in the tropics, who has had in his view the hygrometric condition of the air. These are instances in which, with the same absolute quantity of vapour, every variety of climate is produced by a change only of temperature. As in such cases the change of temperature is due to the expansion of the air, as it rises and is under less atmospheric pressure, the absolute quantity of heat, as well as of vapour, may be the same in an equal weight of the air as in the valley. We may here perceive a curious and important indirect effect of different degrees of atmospheric pressure, besides its direct action on our bodily frame.

On the other hand, considerable, though less varieties, may be produced by different quantities of the *vapour* present; while the absolute *heat* remains the same.

It would be exceeding the limits of my province to enter farther into these natural modifications of the air, and although it was necessary to enumerate the various kinds of air, the characters and action of which we have to recognize, since the physician is familiar with their effects I shall not presume to occupy medical readers with a consideration of them at length; but I may briefly notice each, with the view of establishing the positions which follow.

1. Cold and dry air, though bracing to the healthy, and to some other invalids, may, I presume, be pronounced more or less injurious in the cases of the great majority of pulmonary invalids. Even in such exceptions as those of active hæmorrhage from lungs, is not the exposure, though necessary, often partially counterbalanced by its after-effects? If the air be extremely dry and cold, it is piercing even to the lungs of a healthy person, by the evaporation it excites, added to its conducting power; though its external effect on the skin is not equal in proportion. On the air-passages, in an irritated state, its effect is obvious, adding distress from exsiccation to that from chilling.

2. Cold air, but with its moisture at par, or in that state in which it excites no unusual evaporation, appears the most durably bracing and healthful to others, and even to some pulmonary invalids it is, at certain periods, grateful, when the excitability of the pulmonary membrane is moderate, while at other times, often in the same day, the same air is distressing, and manifestly injurious. This fact, the dependence of which may, in part, be traced on the quantity of animal heat being generated at the time, led me to contemplate an indirect benefit, namely, the recovery of animal heat, from measures the direct effect of which would be the protection of the lungs. Numerous opportunities have been afforded me of observing the realization of this indirect effect in a remarkable degree.

3. Cold and damp air appears beneficial to few, if any persons, either in health or otherwise. Though it may preserve an irritated pulmonary membrane from dryness, it acquires so much more conducting power, from its humidity, as to be doubly chilling. But it is proper here to remark, that we witness always its conjoint action on the lungs, and on the surface: for even with clothing it checks greatly cutaneous exhalations. Were the *skin* under a warm and dry air, we cannot doubt the injurious effect of the former on the lungs, though still obvious and serious, would be lessened.

4. A hot and dry air seems to agree well with many persons for a time, but to be ultimately exhausting to all. Confining myself to its action on the pulmonary membrane, experience, which has not been inconsiderable, has led me to the conclusion that it has no direct tendency to bring on disease in the chest, though I have known catarrh in the pituitary membrane of the nostrils to be caused by it; but when pulmonary irritation is present, it is much aggravated by a hot and dry air. Active pulmonary disease, in such weather in India, makes a rapid progress. In this country, I believe most pulmonics find a very dry air, though warm, injurious. To some, no air seems more so. The trying effects of such air may, I presume, be entirely laid to the charge of exsiccation. The lungs, when irritable, are rarely in a state to enjoy a quick removal of mois-

ture from their membrane. Even in cases of humid asthma, it may be questioned whether a *very* dry air would be suitable. I have seen some cases benefited much by air in an opposite state, and at the same time warm; while in other cases the respiration of a very humid air, though warm, has appeared to cause some oppression.

In air of the fifth kind, namely, warmer than is refreshing to the *healthy*, but of the same tone (or at par) as to moisture, we recognize the usual atmosphere provided in the chambers of pulmonary invalids, who are under judicious management. Since the skin here partakes of the action of the same atmosphere with the lungs, excepting in so far as it is modified by clothing, physicians, while desiring an artificial climate of this character, doubtless provide the best which can be commanded with domestic arrangements, as imperfect as those common in this country as well as in most parts of Europe.

As to the action upon the lungs of air thus simply warm, I cannot omit to notice a question with respect to it, arising as it did in authority meriting at all times much respect. Some years ago, it was argued that if cold air caused irritation in the lungs in some cases, warm air did in others; for that invalids often felt distress, not so much in the open air as after returning to a warm room. All practitioners must have met with such cases, for they are by no means uncommon; but so far from establishing the fact to which they apparently point, they prove the injury of cold air, quite as much, as does immediate distress from it.

Due reflection must surely satisfy us of this; for it will always be found that the distress alluded to arises *after* the exposure of the lungs to the cold, not before it. The air of the same room, which caused no distress before, is now charged with exciting the irritation and cough. May we not perceive, in cases of excitability of the pulmonary membrane, that which we often observe in outward cases, that cold air will in some cause irritation at once, and, in others, mask the irritation, by at first, in a measure, benumbing the surface?

On entering the warm room, this effect being removed, the irritation occasioned by the cold manifests itself in the reaction which takes place.

That cold is the cause we have proof in the fact, that if the lungs are provided with a warm atmosphere while the person is out, on returning home none of the former irritation is perceived. Indeed, so far from being exceptions to the beneficial action of warmth, to no cases is a tempered atmosphere more advantageous.

6. It was requisite to notice, very briefly, the other several varieties of air of marked character, that I might be brought to rest upon that one which I conceive of chief value in the treatment of pulmonary irritation; namely, an air to a greater or less extent warmer and moister than what I have termed air at par, or air of a temperament which is soft or balmy\*, to persons in sound health.

Here it will be right to meet an objection which has been more than once raised to the views I am now advocating—that whatever might be conceded to theory, it is found in practice that a moist atmosphere, though warm, does not in general suit the pulmonary invalid. It is admitted, indeed, that in febrile and irritable temperaments such an atmosphere is beneficial, but it is contended, and established by an appeal to facts, that persons of a languid and debilitated frame are injured by a residence in moist climates, suffering ultimately an aggravation of their pulmonary symptoms by it. Hence the air of most places in Cornwall, and even of the western isles, is not found suitable to many.

This is a very important consideration in the production of an artificial climate, suited to the *whole* body, where the *skin* is to be subjected to the same atmospheric treatment with the *lungs*; for the natural climate, from whence the analogy is taken, enveloping the whole body, acts of course at every point upon it. May we not, however, be prepared to find an atmosphere having this universal operation on the body to be oppressive, and debilitating, on account of a degree of humidity, not at all too much, if it acted only on the irritated part; nay even less than the choicest quantity, if accompanied by suitable warmth?

\* I take the liberty to employ this term in connexion with air, to denote the character and power of action on the body, conferred on it by the proportion of moisture, together with warmth present; the word *temperatures* having by use been confined to the effect on it of heat alone.

That this position is true of a large majority of chronic pulmonary affections of various kinds, overwhelming evidence has been afforded by the experience of late years. The exceptions indeed have been much fewer than might have been expected, owing to the opposite character, in some respects, of the affections benefited.

It would be of the greatest importance in the treatment of diseases, if we could always determine the extent to which outward agents are producing or aggravating the symptoms. To arrive at an exact knowledge of this is beyond our power; but do we adopt the best measures for keeping our minds prepared to seize all the evidence we can of such influence?

Since we find the various indications of disturbed health, named symptoms, prone from causes, some of which are obvious, and others occult, to occur in sets, it is undoubtedly necessary and correct to class these sets of symptoms under different names, and to treat each as a separate disease, with as much steadiness as we observe its character to maintain. The science of practical medicine must, indeed, rest on such a classification.

At the same time would not another classification of symptoms, under their causes, so far as they can be discovered, be also very advantageous; especially as to how far they are intrinsic, arising out of a tendency to disordered action in the system itself, or extrinsic, produced or aggravated by external agents? Though the influence of outward agents is by no means overlooked by the able cultivators of modern medicine, are not some too much disposed to treat their power as secondary, and, through scholastic habit, to acknowledge a certain set of symptoms as a kind of rightful property of a disease? By thus expecting the presence of a symptom, are we not rendered less watchful of external agency in producing or aggravating it? If I may state the experience of one individual mind, I am ready to admit myself to have been greatly under this bias of a system, and to have found an emancipation from it to have opened the prospect of a new field for useful labour. The influence over bodily symptoms of certain external agents acting through the mind, and the grosser influence of others acting through the stomach,

have doubtless received much attention; nor has atmospheric influence over pulmonary symptoms, to which our present subject confines us, by any means been neglected; but I think the power it exercises in the production and maintenance of symptoms is oftentimes far more considerable than is apparent at the time.

I now proceed, therefore, to attempt some inquiry into the power which the atmosphere exercises in the production or aggravation of some of the more general symptoms.

**Cough.** No one can overlook the fact that this symptom is much influenced by the state of the atmosphere, but it is still rather considered a symptom belonging to several affections of the lungs, than as mainly what may be termed an atmospheric symptom. On the one hand we find it to accompany in general all diseases of the lungs, so that it cannot rest upon any peculiarity in any one disease; and on the other hand, we observe each disease in its chronic stage occasionally to want this symptom, which also tends to the conclusion that it is dependent, in part at least, upon some external cause.

If we will allow our attention to be arrested by familiar facts, and will reason upon them, shall we not be led to the conclusion, that, while the disease is a remote cause of cough, by rendering the pulmonary membrane susceptible of irritation, the active cause, or irritant, is at all times, and in every case, to be found chiefly in the state of the air, acting either on the skin or on the lungs, especially upon the latter? To this fact in chronic disease there are very few exceptions. It often happens that some collected secretions appear to cause the cough, for when they are expectorated a temporary relief is felt; but we may almost invariably find the anxiety to expectorate them to be closely dependent on the state of the atmosphere, and indeed their secretion also. Do we not find them irritating in proportion as they grow thick by drying? It is common for a violent fit of coughing in the morning to bring up a solid crusty sputum, which had dried during the night under the constant action of the currents of respired air. In such a case, the sputum is rendered irritating entirely by the air. Collections will often remain a whole night in the chest, causing no distress, if the air respired

is rendered exactly suitable to the lungs, so as to soothe instead of irritate them:—a fact I have frequently noticed. In this case the expectoration is often effected with perfect ease in the morning, and its *collective* amount is always *much less* than if it had been forced up all the night, as fast as it was secreted, by repeated coughing. Now this state of distress may be produced at once by substituting an untempered for the balmy air. Even with the imperfect modification of the air which a bed-room fire produces, nothing is more common than to find the suffering of invalids to commence when the fire goes out in the night; shewing that the cause of the immediate distress is the state of the air. Yet even the best air, produced by ordinary means, is a very imperfect substitute for the proper atmospheric treatment.

In the first place, it is not warmth only which is wanted. In a large majority of cases the air ought to approach, by the addition of moisture, more near to a saturated state; and such air should be administered as uninterruptedly as the warmth. A temporary employment of it, even at the gentle warmth desirable, to be followed afterwards by air of ordinary dryness, may in effect and in principle be compared to a temporary supply of warm, to be followed by breathing cold air. We must look upon air of a warmth and humidity suited to the case, not as a measure of active treatment, the effects of which are to be expected after the employment ceases, but as simply a careful warding off of the grand irritant to lungs in an excitable state—an atmosphere of an unsuitable temperament. If we take this view of the point before us, it becomes obvious that the protection must be *unremitted*.

But in this case of nightly cough there is another reason why all the power of the air, for good or for evil, is not manifested, if by tempering the *whole* air of the room we think our atmospheric treatment completed, and conclude that in any subsequent distress atmospheric causes cannot be concerned. In this, our usual course, we involve the whole body in one atmosphere. If it be elevated to the point which would be perfectly soothing to the lungs (so far as warmth is concerned) it is too likely to cause oppression, restlessness, and fever. Hence, by experience, we

For the irritable lungs, until we had ascertained the fact that a more soothing air could not be commanded for them; and if we found that it could, it should surely be again our primary measure to administer it to them, our medicines being reserved for the removal of any distress that did not subside under its genial influence. Of course it is meant that all active treatment required for the disease, as well as all other regimen, should be employed according to the indications; but it is at the same time unquestionably proper to ascertain (if we can) the whole extent of the atmospheric influence on the symptoms, and remove, as we would a foreign body, any remaining cause of irritation in it, before we attempted to allay the cough by other means.

If even in cases where the air of a room is tempered by a fire, a still further modification of that supplied to the lungs is indicated, with how much force does the argument apply to the numerous cases in which either the fire goes out at an earlier hour, or in which no means at all are employed for tempering the air! How many persons overlook the fact that the state of the atmosphere is the chief cause of their suffering at the time, and often of the disease itself, by its repeated influence, and treat themselves as if their cough depended entirely upon some internal cause, to combat which the stomach was the proper chamber for the conflict! And how strangely do they neglect to consider that they cannot thus repeatedly employ it as the arena for altercations for which its delicate drapery was not intended, without, in time, seriously damaging its walls and floor, and with them every other chamber in the dwelling-house of life. Yet, without any consideration, two-edged weapons are often daily swallowed in some hidden specific, in preference to the employment of measures prescribed or devised by qualified minds!

Thus to employ specifics for subduing the irritability, before we have removed the chief exciting cause of it, may be compared to the act of a native surgeon of India, whom I found applying a plaister of opium and herbs to the foot of a person in great pain, in which there proved to be a very large thorn, causing the distress, the presence of which he had overlooked.

2. *Dyspnœa*.—Difficulty of breathing is another symptom which, next to

cough, appears in chronic affections closely dependent on the state of the air. With the exception of cases where it is the result of extensive disease in the lungs, we find it to vary so greatly with changes in the atmosphere, that we are justified in maintaining the expediency of endeavouring to moderate it by measures directed against irritating properties of the air. These being nearly the same as in the case of cough, the remarks under that head are applicable to dyspnœa. In addition to the immediate distress produced by oppressed respiration, we have to bear in mind, that, if long continued, it cannot fail of acting, indirectly, in a very pernicious manner. The lungs being never supplied with a due quantity of fresh air, an unhealthy condition of the blood is the necessary result. Since the gaseous discharges from the lungs must be limited in proportion, a quantity of matter must accumulate in the blood, which ought to be excreted; in short, a sort of pulmonary constipation is established, the effects of which will not appear trifling to those who bear in mind that the lungs are the grand channel for the discharge of surplus matter from the body, compared with which even the alvine discharge is small. This fact cannot be overlooked by the pathologist. It even struck myself, on my return from a tropical climate, where, amidst many causes of bodily distress, the respiration is in general very free. Here, in England, most pulmonary invalids seemed to be constraining their lungs to make shift with half the natural quantity of air.

3. *Pain*.—That the state of the air is largely concerned as a cause of this symptom is a familiar fact, though not to the extent to which it has a share in producing cough. Nothing is more common in chronic disorders than for pain to be rarely felt, excepting as a consequence of inhaling keen air. When much disease is present, the pathologist discerns a mechanical cause for pain during inspiration; but in the great majority of cases, the state of the air is obviously the chief cause of such pain as is felt during the indraught of air. That the cause is more atmospheric than mechanical, we may conclude from the fact, that the point, or degree of expansion, when the pain is felt, depends much upon the character of the air entering; for, as an apart-

are led to the conclusion that a certain temperature (commonly about  $60^{\circ}$ ) is the best for pulmonary affections: and as a night cough will often still prove distressing, especially in the recumbent posture in bed, we are wont to view it purely as a pulmonary symptom, in which the air cannot be concerned; for we have found, we think, by abundant trial, the best atmosphere for such cases, and even, perhaps, by watchful attention, for the particular case. If it be then purely a symptom of the disease, we conclude that it must be treated medicinally; and resting satisfied with our atmospheric management, our whole attention is wont to be directed to treatment of another kind. The diseases and states of the system in which cough is a troublesome symptom, are so various, and even in the same disease the shades of difference so numerous, that the sagacious and learned physician finds in the discerning of them an inviting field for the exercise of his skill; and it is exercised by such men in a manner worthy of all our admiration. Even a domestic medicine chest will be made to yield perfect relief in such hands, which, when meddled with by the owner, had only served to increase the symptoms, and, perhaps, to aggravate seriously the complaint.

But while it behoves us to appreciate to the fullest professional skill exercised in a proper employment of medicinal and other remedies, the position is not at all altered, that until we have submitted the lungs to a different atmospheric treatment from the skin, we cannot have ascertained the extent to which the air may have been the cause of the cough on the one hand, neither can we know on the other the amount of relief which may be at our command, if we can administer to the organ an atmosphere designed for it alone, so as not to be arrested in our progress towards its attainment by the oppression it would occasion if the whole system were subjected to its action. The case is nearly the same as if we had never been able to arrive at the employment of fomentations to irritated parts, because experience had established the fact, that placing the whole body in a hot bath was injurious in such cases by exciting fever.

It will not surely be argued, if the cough can be relieved by internal

medicines or by counter-irritants, that we may be satisfied with an atmosphere as near to that desirable for the lungs as one that envelops the whole body admits of being made; for though the injurious effect of medicine is often far less than the continuance of distress, so that the benefit, upon the whole, is great, we must not overlook the fact that, viewed apart from their object, medicines repeatedly taken are injurious; and as they decline in their effect by use, in many chronic cases, with a constantly decreasing effect, we have an accumulating injury from them, until disorder of the stomach is superadded to and aggravating that of the lungs. That was surely good advice to a friend, to take every grain of medicine that was necessary, but not one grain more.

If the fact should be granted that in *many* cases (I will not say *all*), after the usual precautions for tempering the air of a room have been adopted, atmospheric influence has still a share in producing the cough, before medicine is given to relieve this symptom, ought not our efforts to be directed towards the removal of the remainder of such atmospheric influence? Ought we not, upon principles strictly medical, to consider the first indication to be the employment of all the resources of science and art for rendering the air administered to the lungs as soothing as possible to them, and then to employ drugs to perform whatever supplementary work remained to complete the relief? The question is one only of degree. The case forms part of a system, at one end of which would be treating a pulmonic patient in a barn; where, in spite of the weather, it would, no doubt, in many cases be possible to effect a cure by the power of medicine, but the treatment would have to be doubly trying. Here the causes aggravating the symptoms would be obviously atmospheric, but they would not amount to the whole influence of the climate, for the patient would have to lie out of doors to be subjected to it; they would only be the remaining influence which the shelter of the barn could not modify. Since we would not rest satisfied with the atmosphere of a barn as sufficiently artificial, but as a primary measure would bring the sufferer into a bed-room, so neither should we stop here, and rest contented with this atmosphere as sufficiently artificial

for the irritable lungs, until we had ascertained the fact that a more soothing air could not be commanded for them; and if we found that it could, it should surely be again our primary measure to administer it to them, our medicines being reserved for the removal of any distress that did not subside under its genial influence. Of course it is meant that all active treatment required for the disease, as well as all other regimen, should be employed according to the indications; but it is at the same time unquestionably proper to ascertain (if we can) the whole extent of the atmospheric influence on the symptoms, and remove, as we would a foreign body, any remaining cause of irritation in it, before we attempted to allay the cough by other means.

If even in cases where the air of a room is tempered by a fire, a still further modification of that supplied to the lungs is indicated, with how much force does the argument apply to the numerous cases in which either the fire goes out at an earlier hour, or in which no means at all are employed for tempering the air! How many persons overlook the fact that the state of the atmosphere is the chief cause of their suffering at the time, and often of the disease itself, by its repeated influence, and treat themselves as if their cough depended entirely upon some internal cause, to combat which the stomach was the proper chamber for the conflict! And how strangely do they neglect to consider that they cannot thus repeatedly employ it as the arena for altercations for which its delicate drapery was not intended, without, in time, seriously damaging its walls and floor, and with them every other chamber in the dwelling-house of life. Yet, without any consideration, two-edged weapons are often daily swallowed in some hidden specific, in preference to the employment of measures prescribed or devised by qualified minds!

Thus to employ specifics for subduing the irritability, before we have removed the chief exciting cause of it, may be compared to the act of a native surgeon of India, whom I found applying a plaister of opium and herbs to the foot of a person in great pain, in which there proved to be a very large thorn, causing the distress, the presence of which he had overlooked.

2. *Dyspnœa*.—Difficulty of breathing is another symptom which, next to

cough, appears in chronic affections closely dependent on the state of the air. With the exception of cases where it is the result of extensive disease in the lungs, we find it to vary so greatly with changes in the atmosphere, that we are justified in maintaining the expediency of endeavouring to moderate it by measures directed against irritating properties of the air. These being nearly the same as in the case of cough, the remarks under that head are applicable to dyspnœa. In addition to the immediate distress produced by oppressed respiration, we have to bear in mind, that, if long continued, it cannot fail of acting, indirectly, in a very pernicious manner. The lungs being never supplied with a due quantity of fresh air, an unhealthy condition of the blood is the necessary result. Since the gaseous discharges from the lungs must be limited in proportion, a quantity of matter must accumulate in the blood, which ought to be excreted; in short, a sort of pulmonary constipation is established, the effects of which will not appear trifling to those who bear in mind that the lungs are the grand channel for the discharge of surplus matter from the body, compared with which even the alvine discharge is small. This fact cannot be overlooked by the pathologist. It even struck myself, on my return from a tropical climate, where, amidst many causes of bodily distress, the respiration is in general very free. Here, in England, most pulmonary invalids seemed to be constraining their lungs to make shift with half the natural quantity of air.

3. *Pain*.—That the state of the air is largely concerned as a cause of this symptom is a familiar fact, though not to the extent to which it has a share in producing cough. Nothing is more common in chronic disorders than for pain to be rarely felt, excepting as a consequence of inhaling keen air. When much disease is present, the pathologist discerns a mechanical cause for pain during inspiration; but in the great majority of cases, the state of the air is obviously the chief cause of such pain as is felt during the indraught of air. That the cause is more atmospheric than mechanical, we may conclude from the fact, that the point, or degree of expansion, when the pain is felt, depends much upon the character of the air entering; for, as an apart-

ment grows warmer, an invalid will often breathe more and more deeply without pain. While this is a matter of common observation, it will not do to conclude that the air is rendered sufficiently suitable when all pain ceases, for upon trial we shall frequently find that the cough, which is commonly still present, may be also removed by an atmosphere of a much more refined temperament (if I may be allowed the expression) than will suffice for causing pain to cease.

The fact is not overlooked, that an in-draught of sharp air will sometimes cause pain, without exciting any cough; yet I presume it is correct as a general truth, that where pain arises from the state of the air, a more ungenial air is required for producing it, than would excite cough; and the reason is obvious. Air, if removed in the smallest degree from that balmy state which would produce no sensation in the excitable membrane, may cause the uneasy tickling which induces coughing, but it must be of much rougher quality in order to irritate the membrane to the point exciting pain.

3. *Expectorations.*—While every affection of the lungs has a discharge more or less characteristic of it, and while it is admitted that this is not so much an atmospheric symptom as cough, even a casual observer may soon perceive the fact that the state of the air has a large share in determining both the quantity and the quality of the discharges in every case. Some invalids may almost tell which way the wind blows, whether from a damp or dry quarter, by the state of their rheum. Since the character of the discharges has so close a connexion with the progress of the disease, we have in this symptom also a ground for anxiety, that so long as their undue excitability continued, the lungs should never be visited by any but a genial air. Now there is no fact which it is of more importance to dwell upon, or which is more irrefragably true (however little attention it may have commanded), than that, in most chronic affections of the lungs, an atmosphere, if it be well suited to the exterior surface, will not prove of that temperament (*i. e.* thermometric and *hygrometric* condition), which is qualified to exercise the most genial influence possible upon the pulmonary membrane while in an irritable state.

REMARKS  
ON  
CERTAIN DISEASES OF THE EYE,  
ILLUSTRATED BY CASES.

BY JOHN CHARLES HALL, M.D.  
Member of the Royal College of Surgeons,  
London, &c. &c. &c.  
(For the Medical Gazette.)

III.—*Iritis continued; use of iodine and salicine in certain forms of it.*

IN the last paper we examined the anatomy of the iris, and the causes, symptoms, and effects of acute iritis. Although I have insisted on the necessity of bleeding in the early stages of it, the student must remember that bleeding alone will not cure the disease, and if he relies solely on an antiphlogistic plan of treatment, will have to regret the loss of vision in many of the cases he may be called upon to attend. The sheet-anchor of the surgeon is calomel; and this must be given until the system is thoroughly affected. But can we always employ this remedy? No; constitutional systems often point out the impropriety of using it at first: the state of the patient must be carefully attended to, the general health improved, and mercury afterwards given. I am, of course, now speaking of the chronic rather than the acute forms of the disease. When we cannot, in acute iritis, for reasons already stated, give calomel internally, the blue ointment, combined with opium, must be rubbed in every night and morning, and the following medicine given regularly, as directed:—

R. Potass. Iodidi, gr. ij. ad grs. iv.;  
Syr. Aurantii, ʒi.; Aquæ Rosæ, ʒix.  
M. ft. haustus ter die sumendus.

This is a very valuable remedy, and, next to mercury, the best we can employ. In every case I am called upon to attend, I give small doses of the above, in addition to the calomel and opium, and with the greatest possible success.

The cases I have seen (and they certainly amount to several hundreds) of acute iritis, not only in private practice but also in the hospitals of London and Paris, warrant me in thus strongly urging the employment of mercury in the treatment of this disease. If used properly, and the disease taken in time, I am fully persuaded, nay, even cer-

tain, that in by far the greater number of cases useful vision may be preserved; and therefore the mercurial plan being certain, ought always to be used. The antiphlogistic plan is uncertain, and ought never to be altogether depended upon. Bleeding largely, and then rapidly affecting the system with mercury, is a plan of treatment that holds out every prospect of success in favourable cases—I mean cases in which we see the disease in its first stage; and even when some progress has been made, very useful vision is frequently obtained by steadily going on in the use of calomel and opium, and the preparation of iodine already mentioned.

Strongly as the use of mercury has been insisted upon, some caution is, nevertheless, required, and the case must be carefully watched, if the desired end is to be accomplished. If the disease advances, the dose must be increased; if checked, and the system has become affected, it must be diminished. The abuse of good remedial agents has brought them into disuse, and the advocates of them come in for no small share of censure, through the ignorance of those who misemploy them. In certain injuries, bleeding is doubtless useful, to prevent, or if present to subdue, inflammatory action; but, if carried too far, the powers of nature may be exhausted, and the curative process altogether prevented. So, in the exhibition of mercury for the cure of iritis, it often fails to afford relief, because carried too far, and thus begets, or, at any rate, supports, a peculiar state of the system, under which it is quite impossible a healthy local action can exist. It will, therefore, be necessary to examine the condition of all the important organs of the body, and the way in which they perform their several functions, before commencing a course of mercury; and the form of its exhibition, and the strength of the dose, must be regulated accordingly. Here I feel my inability to give plain directions to the student; the necessary information cannot be given in the pages of the *MEDICAL GAZETTE*. The disease must be studied at the bedside of the patient, in the wards of our hospitals; the volume of nature must be read; its pages are open to the humblest inquirer, and amply will his researches be repaid. Could the candidate for the diploma of the College of

Surgeons, and the College of Physicians, be examined, partly in the wards of an hospital, and made to point out the nature of the disease, its cause, symptoms, probable result, and the treatment necessary, the trade of the grinder would soon cease, his wheel emit none of its brilliant sparks, and in the place of men crammed for the occasion, we should have practitioners who would be alike ornaments to the profession and useful to the public. Much as I have written for the *MEDICAL GAZETTE*, I have never mentioned medical reform, being satisfied with things as they exist at present; at the same time, I venture to throw out this hint, and were it adopted, think much good would result from it. We have next to consider

## II.—*Chronic Iritis.*

In speaking of chronic iritis, I do not allude to that disease which is sometimes found after the more severe symptoms of iritis have passed away. In addition to this, a form of the complaint is now and then present, which, from the slowness of its growth, the mildness of its symptoms, and the length of time it continues, must be termed chronic iritis. It will be well to distinguish between the two forms of this malady; all the train of symptoms already pointed out are much less acute, and far more slow in their development. In acute iritis the disease may be fully established in twelve or twenty-four hours. In this form of it as many hours may have passed away, and no progress made. The red zone of vessels is far less marked, and appears broken in many places (*an interrupted belt*); and although the symptoms described as pointing out an attack of acute iritis are present, they are far less marked, and the power of vision is less impaired; but, if suffered to run its course, by degrees the organ will become imperfect; and so slowly, so insidiously, does the disease creep on, that the eye may be all but lost before the patient has discovered it. In many cases the other eye, at this stage of the attack, becomes dim, and then the patient applies to his medical attendant, and the mischief is discovered. Little pain then is experienced; there is little or no intolerance of light, and no increase of lachrymation, or, if it exists at all, it is too slight to arrest attention.

It will be necessary further to remark, that in chronic inflammation of the iris (not the result of the subsidence of an attack of acute inflammation), no change takes place in the colour of this membrane. I have seen lymph deposited, the pupil closed, and vision destroyed, from long-continued and repeated attacks of inflammation of the iris, without its having lost either its colour or peculiar polish.

It not unfrequently happens that some patients are repeatedly affected with slight attacks of iritis, which, in the end, either altogether destroy vision, or seriously injure it, by rendering the transparent structure of the eye opaque and muddy. In these cases it is absolutely necessary at once to subdue the attack of inflammation; secondly, to ascertain, and if possible to remove, the constitutional derangement on which it depends, and to prevent the patient using the eye in any way that may tend to injure vision; and, lastly, by establishing some permanent counter-irritation, as a blister behind the neck, or a seton, to preserve the eye from additional attacks of inflammation. It will also be necessary to pay particular attention to prophylactic measures, for when once this form of inflammation has set in, it is very liable to return again. It is a singular fact, nevertheless one that is well authenticated, that this disease runs in families. Mr. Middlemore remarks,—“I am acquainted with several families, the brothers and sisters of which are blind from relapses of chronic iritis: three brothers and two sisters in one family have lost all useful vision from relapses of this disease, and the eldest of them is not more than 50 years old.”

This disease must be looked upon as a less acute form of iritis (of simple acute iritis), but, as already seen, frequently leads to loss of vision. I have at this moment the son of a farmer under my care (Mr. Roberts, of Everton) who has repeatedly suffered from attacks of chronic iritis. On the present occasion the disease had advanced slowly, and too insidiously to create uneasiness; a month passed away before any one examined it, and, when I saw him, it had made considerable progress. Regarding this as a very severe case, I treated it accordingly, and with the best results. In truth, the disease is inflammation, has a tendency to produce the effusion of lymph and the

destruction of the pupil, and must consequently be attacked by the same remedies as acute iritis. It will not be necessary to bleed to the same extent; but in all cases where the patient is young, and the pulse sufficiently full, I prefer bleeding from the arm to the application of leeches in the first instance. After this, mercury in some form or other must be given: it will not, however, be necessary to give it in the same doses as in acute iritis: it is much better, in fact, gradually to affect the system with doses of blue pill, combined with opium, hydrarg. c. creta, and Dover's powder, or any other form of mercury that may be found suitable to the peculiarities of the patient's constitution.

Some will not bear mercury in any form—others are so feeble that it is impossible to administer it; but we have a powerful remedy in turpentine, which we shall more particularly consider when speaking of syphilitic iritis.

Mr. Tyrrell well remarks, in speaking of the causes of chronic iritis, “That the disease sometimes commences in this form, from the same causes as produce the acute stage; but very frequently it is induced by reducing the acute disease *by antiphlogistic means, without the aid of mercury*: the redness and pain being relieved, and the vision in a degree improved, the patients are considered as cured; whilst this insidious but destructive stage still exists, and goes on to occasion the mischief”—which I have described.

Now and then a patient is brought to me in whom the antiphlogistic plan of treatment has been carried as far as possible, and yet the disease has still gone onwards, and the power of vision is all but lost. I have seen such cases many times, and the blanched lips, feeble pulse, pallid countenance, and cold extremities, clearly proved the extent to which depletion had been carried. How are we to treat a patient applying for relief under such distressing circumstances? If the eyes are examined the irides will be found dull, the pupils small and lozenge-shaped, and fixed from adhesions of the pupillary margins to the anterior capsules of the lenses; the zone of vessels round the cornea will be distinct, broad, and of a dirty dull-red colour: this is occasioned by the distension of the sclerotic vessels with red blood.

It is clear we cannot give mercury

here; and yet we cannot cure the disease without it. The patient will, perhaps, complain of great depression, loss of strength and appetite, the hands tremulous, the gait feeble and unsteady: night-sweats, and other symptoms, indicate a great want of general power. He will very likely experience, also, some pain in the eye and over the eyebrow. This may be removed, by rubbing in, night and morning, some blue ointment, combined with opium and belladonna. Under any circumstances belladonna must be rubbed upon the eyebrow two or three times a day.

Our first efforts must be directed to improve the state of the system. A generous diet must be allowed, the bowels kept open with colocynth and henbane, and some mild tonic administered. I generally give the iodide of iron, or the pot. iodid. with infusion of chirayta, or sulphate of quina and infusion of roses.

In a short time, the general health, under ordinary circumstances, will improve. We must then give, in addition to this, small doses of mercury with chalk, and they must be gradually increased, and a blister applied to the back of the neck. This plan of treatment holds out the most reasonable prospect of success; but it is to be feared in such cases complete recovery in the majority of patients is not to be hoped for.

After an attack of either acute or chronic iritis, should the eye appear weak, particularly if there remains any degree of chronic conjunctivitis, the superficial vessels being in an enlarged and atonic condition, the eye may be bathed with vinum opii and water, or a weak solution of nitrate of silver, which will remove the "weakness of the eye" the patient complains of, and restore it to its normal state.

### III.—*Iritis from Wounds.*

The symptoms and results of iritis from injury are the same as in the forms already considered, with the addition of the evidence of some injury.

It will be necessary to remove, if possible, the foreign body; but this plan of procedure will depend in a great measure upon its size, situation, and nature. If very small it had better be allowed to remain, unless its removal can be effected very easily, as it will in all probability become encysted. If

large, it will be better to remove it, unless of a composition which the aqueous fluid can dissolve.

The treatment of this form of iritis will not differ from that already pointed out, when speaking of acute iritis. In addition to bleeding, I wish strongly to advise the use of calomel, for although it does not entirely destroy the inflammatory action during the presence of the extraneous body, nevertheless the judicious employment of mercury has the power of considerably retarding the injurious results of iritis. The treatment of this form of iritis may, perhaps, be best illustrated by the following very interesting case:—

CASE III.—Mr. W——, of Retford, applied to me in the summer of the past year, in consequence of an injury he had sustained in one of his eyes. He stated that some time ago he had injured his eye with a small and very sharp piece of iron—that he had taken some opening medicine, and applied a blister to the forehead over the suffering member. It is needless to point out to the veriest tyro the folly of placing a blister in such a situation during an acute attack of inflammation of any of the textures of the eye.

On examination, a small wound of the outer margin of the cornea could easily be discovered, but no part of the foreign body remained: four or five days had passed since the accident. He complained of great pain—could hardly look at the light for a moment; the tears flowed continually from the eye; the whole of the cornea was clouded; the iris, as well as I could see, from the circumstances already alluded to, contracted and discoloured; it had lost its peculiar brightness, and appeared dead; a portion of the pupil was filled with an opaque deposit, and hypopion also existed; the red zone of vessels and other distinctive marks of iritis were present. He was largely bled; leeches were applied afterwards, and the system rapidly affected with calomel: belladonna to the eye-brow, and three grains of potass. iodid. three times a day. Under this treatment the case gradually improved, and the poor fellow recovered his sight perfectly: the only thing to regret was a slight opacity caused by the wound in the cornea; but this was not sufficiently large to interfere very materially with useful vision.

### III.—*Specific forms of Iritis.*

I must defer for the present a very minute examination of syphilitic iritis, and also of cases in which inflammation of the iris comes on in patients labouring under a gouty diathesis. I will, however, venture to express the opinion that in the great majority of cases, in which an attack of syphilitic iritis comes on, no mercury has been taken for the cure of the primary disease. It has been remarked that, in addition to pure syphilitic iritis, there is another disease which very closely resembles it, and which has been termed pseudo-syphilitic, as being compounded of two states of the system (as regards its cause), viz., the syphilitic and the mercurial. Mr. Travers here observes that, although "iritis is frequently met with where no mercury has been taken, it is seldom or never seen as a sequela of syphilis, where the system has been brought under the influence of mercury." Mr. Hewson, who has devoted much attention to an examination of the diseases of the eye, writes—"iritis, the result of syphilis, is rarely observed except where mercury has been inefficiently or inadequately administered." Mr. Middlemore observes, with his usual force and accuracy, "from a careful review of all the cases which have fallen under my observation, it appears to me that iritis occurs much more frequently after a venereal sore has been healed without mercury, than when this medicine has been used for its cure, and also that it occurs with the greatest severity, as well as with the greatest frequency, as one of the secondary symptoms of syphilis, when the original disease (the chancre) has been allowed to heal without the administration of hydrargyrus. It is said that inflammation of the iris may occur as a consequence of those anomalous ulcerations about the genitals, which are presumed to arise independently of venereal affections; just in the same way as pure syphilitic iritis results from genuine chancre. This may be the case. I am not prepared to disprove the opinion; but I certainly do not believe it to be correct."

A very careful examination of this subject has fully convinced me that iritis comes on much more frequently after chancre where no mercury has been given, and also that it is much more severe. If the reader examines

the cases of syphilis reported by Dr. John Thompson, and also by Mr. Rose, treated without mercury, iritis is mentioned as a not very unfrequent secondary affection. I have heard of cases in which women have been attacked with iritis, having contracted venereal disease from their husbands, and through delicacy, or ignorance of its nature, failed to mention it to their medical attendant. Mr. Middlemore quotes a case originally recorded in the *Medico-Chirurgical Review*, where iritis occurred in a nurse from syphilitic ulceration around the nipple, produced by suckling a child whose mother had the venereal disease prior to its birth, and this nurse had taken no mercury for the sore around the nipple. This writer also quotes another case exactly similar.

Mr. Lawrence has noted one peculiarity in syphilitic iritis, viz., that the inflammation is always of the adhesive kind, for "he has never observed it to terminate in the effusion of pus:" and this fact was proved in the case of a lady, who had inflammation of the deeper-seated tunic, from the extension of the inflammatory action, which originally constituted syphilitic iritis, and which ended in the bulging of the sclerotica, which appeared distended with pus. An opening was made, but none was discharged, and Mr. Lawrence concluded that it was lymph, and not pus.

In the treatment of syphilitic iritis it will be advisable to bleed generally, or locally, according to the condition of the patient, and afterwards freely to evacuate the bowels. By the former plan the circulation will be lowered, by the latter the system prepared for the exhibition of mercury, which must be administered in such doses as the peculiar nature of the case points out.

Mr. H. Carmichael, of Dublin, has advised in certain cases the administration of turpentine (that is, in cases where mercury cannot be given) as a valuable substitute for calomel: he advises it to be administered in this form.

*R. Olei Terebinth. Rect. ʒj. ; Vitellum unius ovi, tere simul. et adde gradatim emulsionis amygdalarum ʒiv. ; Syrupi corticis Aurantii ʒij. ; Spir. Lavandulæ. compositi ʒiv. ; Olei Cinnamomi guttas tres vel quatuor. Misce. Sumat cochlearia larga duo ter in die.*

It is needless to remark that bella-

donna must be applied to the eye-brow as in the other forms of iritis, and blisters may be tried in its more chronic form; but in no kind of inflammation of the iris are they productive of so little good.

#### IV. *Scrofulous Inflammation of the Iris.*

The very great difficulty we have in obtaining a view of the eyes of children, frequently causes this disease to be overlooked, and considerable progress is often made before its true nature is sufficiently ascertained. Mr. Lawrence remarks, "in strumous children inflammation commencing in the external parts of the eye extends to the iris. This strumous iritis is usually attended by some change in the structure of the cornea. The opaque state of the cornea prevents you from observing the changes taking place in the iris, so that the very existence of iritis is not known until it has gone through its course, and come to an end."

But from the frequency of its occurrence it ought always to be suspected, and the most careful examination made, and iritis will, in the great majority of cases, be found combined with inflammation of the cornea, and also of the membrane covering the aqueous humour in strumous children. Its effects are similar to those produced by the other kinds of iritis, and may lead to a change in the colour of the iris, to contraction and closure of the pupil, adhesion of the iris to the surrounding parts, or to staphyloma.

But how are we to treat such cases? Bleeding and mercury, to the extent already advocated, would make matters worse. In the early stages, in a moderately strong child, a few leeches may be applied to the lower lid, and the bowels must be freely opened with a full dose of calomel and rhubarb. I think the best form of administering mercury in these cases is in the form of the blue powder—three grains of hydr. c. creta, five of sesquicarbonate of soda, and two of Dover's powder, may be given every night at bed-time. If we give calomel, push it to ptyalism, and still go on with it, under the idea that it is the proper remedy, I apprehend the patient's constitution will, in nine cases out of ten, be seriously injured, and vision either altogether lost or very seriously impaired. In such cases the exhibition of the sulphate

of quinine is followed by the happiest effects. As the constitution improves under its influence, vision improves also, and the improvement of the general health of the patient appears simultaneous with the improved condition of the eye. The salicine is also a valuable medicine, and may be given where quinine disagrees. I knew a lady suffering from a disease of this nature in which quinine could not be taken, but where the salicine was administered with the happiest effects. It appears that it does not possess any alkaline principle, similar to quina or cinchona, and is entirely inferior to them. M. Magendie remarks, "it is a powerful febrifuge, as I have verified in numerous cases of intermittent fevers at the Hôtel Dieu. I have frequently found it succeed when the sulphate of quinia has failed, and vice versa."

The hydrochlorate of baryta has been highly spoken of, both by Mr. Phillips, in his Lectures on Surgery, and also by Dr. Payan, as a valuable remedy in strumous ophthalmia. Lisfranc also speaks in high terms of its excellent effects. I have only as yet tried it in one or two cases, and cannot therefore speak from experience of the advantages attending the administration of it, and I am less inclined to do so from having repeatedly witnessed the advantages derived from the remedies above mentioned, more especially the sulphate of quinine.

The local remedies are the same as in the other forms of iritis, and are only useful where you have spasm of the lids: opium and warm water, as hot as can be borne, will frequently afford relief, and give great comfort to the sufferer. In the latter stages of the disease great irritability of the organ is often complained of, and this may easily be removed by the daily use of the vinum opii, alone, or combined with a weak solution of the nitrate of silver; half a grain to an ounce of water.

In speaking of syphilitic iritis, blisters were considered of little use: in this form (strumous) of inflammation of the iris, counter-irritation must always be employed. As soon, therefore, as the inflammation is somewhat checked by the application of leeches, and the administration of a brisk purgative, blisters should be applied behind each ear, or to the back of the neck, and

# MR. WRIGHTSON'S CASE OF DELIRIUM TREMENS AND

kept open; or, what is better, a small seton may be placed in the neck or arm: this of course will leave a mark, and must not be attempted, if the patient is a young lady. Air and exercise, under proper regulation, must be light, and easy of the body must be sponged with warm water, and rubbed with a rough cloth, and every measure adopted to improve the general health, and to remove that peculiar morbid disposition on which the disease is essentially dependent. It is only necessary to remark, that, in the more severe cases of iritis, the room must be darkened, and when it is necessary to examine the eye, it must be done as soon as possible; nor must a full beam of light be allowed to beam directly upon it, nor is it right that the weakened organ should be long exposed to its influence. Of course, during the active stage, the strictest attention must be paid to the diet of the patient; little or no solid food must be taken; in fact, the most rigid fever diet of our hospitals must be enforced: this, in private practice, will be difficult to accomplish, and, if not attended to, will render, in a great measure, useless the best possible treatment. It will therefore be necessary that the importance of attending to his diet should be enforced, in the strongest possible manner, by the medical attendant, and if told that the restoration to sight, or loss of vision, will entirely depend upon the strictest attention to the orders given, few will be so foolish as not to obey them; if they do, the surgeon will have the satisfaction of knowing that he has done his duty, and the patient may one day have to lament most bitterly his extreme folly.

(Of course every case, in each division of iritis, will present some varieties; no two cases are exactly alike; it will therefore be quite impossible for me fully to point them out. On reading over these papers, already extended beyond the limits at first marked out, I have detected many omissions that want of space renders it impossible now to enter upon; in truth they are only a skeleton map for the student to fill up from time to time, from an extensive field presented for his research by

diseases of the eye. The subject is far from exhausted, and I hope to return ere long to its investigation.

Retford, March, 1842.

## DELIRIUM TREMENS AND FRACTURE OF THE SPINE.

By R. WHITE WRIGHTSON, Esq.

In medical charge of the left wing 3rd Battalion Artillery.

(For the Medical Gazette.)

A EUROPEAN was admitted into hospital on the 24th October, 1841, with delirium tremens. The nervous excitement was excessive; the tongue dry and thickly coated; bowels confined; constant nausea, and pain over the stomach. He had been drinking four days. Calomel and opium, followed by the ol. ricini and ol. crotonis, were prescribed, and on the following day he was much better, although the nervous excitement was still great. The above treatment was followed till the 27th, when all the symptoms appeared alleviated; and after an opiate in the evening, he was tranquil, and fell asleep about 9 P.M. After sleeping an hour, he suddenly awoke in great fright, under the impression that fiends were dragging him to the regions below, rushed past the orderly in attendance, and threw himself from the veranda of the third story of the hospital, a height of 35 feet.

On examining the back, it was found curved forwards; there was a deep indentation over the third lumbar vertebra, and considerable swelling over the first and second. The lower extremities were in a semiflexed position, sensible to the touch, and he could extend the legs voluntarily. The pulse was small and labouring—75; skin cold, and perspiring freely: flexion and extension of the limbs, or the slightest pressure over the loins, gave him the most intense pain: there was no involuntary escape of the urine or fæces. Extr. opii. gr. iv., with stimulants of ammonia, æther, and camphor, were prescribed, with some brandy and water at intervals. As the pulse rose leeches were applied. A 12 P.M., the leeches were removed, in consequence of the pulse not improving: great tumefaction now supervened. The de-

lirium was quite subdued, and he expressed great desire to be attended by his priest. His intellect was quite undisturbed.

26th, 6 A.M. — The pulse much stronger; the body warm; the belly full and tumid: complains of great pain in the back and left side. The lower extremities continue quite sensible to the touch, and retain the power of flexion and extension. The urine was passed in the bed, but he could control the flow when so disposed.

R. Ol. Ricini, ℥iss., to be taken immediately. Ol. Ricini, ℥iss.; Ol. Terebinth. ℥iv.; Magnes. Sulph., ℥ss; Aq. lbss., to be used as an enema, and hot fomentations to be applied to the belly.

At noon, he again became exceedingly low, requiring stimulants. The bowels acted soon after the enema. The urine was retained, and on separating the legs for the purpose of introducing the catheter, the left leg was seized with severe spasmodic pain along the course of the anterior crural nerve, which immediately subsided on bringing the legs together. The urine drawn off was mixed with grumous blood. During the afternoon, the lower extremities were quite cold, and vitality was at a very low ebb, requiring the continued use of stimulants. At 10 P.M. the bowels had been freely moved, and a considerable quantity of urine passed with the assistance of the catheter. The pulse soft and regular; the lower extremities not so cold; and he was disposed to sleep.

29th.—Passed a good night; bowels rather inactive; urine passed voluntarily, but he was unable to move the left leg. Sensation in both remained perfect. He could now lie straight in bed. At 6 P.M., he had some difficulty in passing his urine. Thermometer in axilla, 100°; in the ham, 96°.

30th.—Complained of thirst: tongue furred; pulse full and strong; skin hot: he was freely purged, and had saline diaphoretic medicine, and at bedtime took pil. hydr.; pulv. antim., aa. gr. v.; calomel. et extr. hyoscyami aa. gr. iij.

31st.—Passed a very restless night; reaction considerable; skin hot; pulse strong, full, and somewhat hard; pain in the back and left leg, which comes

on in spasms; felt more severely along the anterior and inner part of the thigh and knee. He was bled to ℥viij.; twelve leeches were applied to the loins. Ordered 3i. pulv. jalap. co., and to continue the diaphoretic medicine.

At 6 P.M. the pulse was less frequent—90, and regular; skin cool; tongue clean, but rather dry in the centre; bowels freely relieved, and the urine drawn off contained less blood; no pain in the back, but numbness and inability to move the left leg. At bedtime he had extr. hyoscyami, gr. iij.; extr. opii. gr. ss.

Nov. 1st.—In the early part of the night he was restless, and after taking the pills he became worse, and a degree of low muttering delirium came on. The pulse continued good; skin cool. At 5 A.M. he suddenly became insensible; breathing quick and stertorous; pulse imperceptible; skin cold; countenance livid; urine and fæces passed involuntarily. He continued in this state, and died at half-past seven.

*Sectio cadaveris, twelve hours after death.*—The body was placed in a supine position, to prevent any post-mortem congestion or gravitation of blood towards the spine; and, with a view to the more full examination of the extent of injury, the spine was first examined.

*Back.*—On removing the integuments, a large quantity of coagulated blood was observed. This occupied a diamond-shaped space, bounded anteriorly by the anterior superior spinous process of the ilium, its inferior point being the centre of the sacrum, whilst superiorly it reached the last dorsal vertebra, extending along laterally by the false ribs. The weight of this coagulum was ℥iij. Blood was extensively extravasated amongst the muscles of the back generally, even to the neck, but especially under the tendons of the latissimus dorsi and trapezius. The spine was divided at the last dorsal vertebra, and the lower part, with the sacrum attached, was removed. The whole spinal canal was laid open above this division. The cellular membrane connecting the theca to the canal was of a vermilion hue. The external appearance of the theca healthy. On being slit open from the occiput downwards, its superior portion had a healthy pearly look; but this was lost on approaching the lower part, where

the membrane was of a redder colour. The medulla spinalis, at its upper part, was firm and healthy, but softer at its lower portion, and, indeed, was quite pultaceous. The lumbar portion exhibited a more injected state of the loose cellular membrane external to the theca, and clots of blood surrounded the nerves as they made their exit. The serous surface of the theca was highly vascular, and stained of a deep blood hue. The nerves seemed much thinned opposite the fractured and loose portions of the body of the vertebra, which must have compressed them on any change of position of the patient. The body of the fourth lumbar vertebra had been completely crushed to pieces; a large scale projected anteriorly, and must have been detached but for its connection with the anterior ligament. The spinous process was fractured through its whole length, and the interspinous ligament and muscles completely disrupted. The articular processes were on both sides fractured; and yet, notwithstanding the force which had thus smashed every thing both before and behind this vertebra, the centre portion of the body was in its place.

**Head.**—There was no congestion of the scalp; the external appearance of the dura mater was healthy: considerable effusion of serum between the arachnoid and pia mater gave it the appearance of a *blistered surface*. There was no opacity or thickening observed. The ventricles contained an ordinary quantity of serum, but had a soddened appearance, and the effused serum had probably escaped by the spine, as the medulla oblongata was much shrunk, and the little finger could be easily passed between it and the canal. The substance of the brain somewhat softened, and numerous bloody points appeared on slicing the white portion, which were quickly renewed if wiped off. The veins generally congested.

**Abdomen.**—Very extensive effusion of blood existed under the peritoneum, on both sides of the spine; the capsule of Glisson was distended with blood; two considerable patches of extravasation on the anterior surface of the liver; bloody effusion around each kidney; both iliac regions distended with blood, particularly in the course of the large nerves and vessels; liver

healthy, perhaps slightly softened; kidneys of an uniform red colour; the cortical part scarcely to be distinguished from the other substance; the pelvis of both contained effused blood; bladder had a considerable quantity of blood effused at its posterior part, behind the peritoneum. Its mucous surface was of a light rose colour, and contained about  $\frac{3}{4}$  of bloody urine.

**Chest.**—In the intercostal spaces on both sides of the spine there was a quantity of blood effused, and some old adhesions were observed on the right side. The lower lobes were much congested and engorged.

**REMARKS.**—The universal effusion from the serous surface of the brain and its membranes, and the shrunk state of the medulla oblongata, are very characteristic of delirium tremens; and as it appears the man was not an habitual drunkard, I am the less surprised that the mischief was confined to serous effusion, no opacity or deposition of lymph being observed. Notwithstanding the extensive injury, there was no appearance of any reparative process having commenced. This must be accounted for by the low state of vital energy—the result of continued over-excitement.

Had there been effusion of lymph, any formation of pus, any of that preparatory congestion which precedes the reparatory process, compression, partial and consequently destructive, must have taken place; but it is clear none such did occur, except mechanically and temporarily, the effusion on the brain and spinal marrow being attributed solely to the delirium. The coldness of the extremities observed on the 28th, the partial loss of power over the bladder, and the entire loss of motion in the left leg on the 29th, are satisfactorily accounted for by the dissection. The reaction seemed to be completely established on the 31st, and as no cerebral excitement had been noticed for several days, bleeding, it was hoped, might have been beneficial; but, perhaps, it would have been better omitted, as only serous effusion had taken place.

Fort William, Calcutta, General Hospital,  
Nov. 8th, 1841.

## CASE OF CAROTID ANEURISM.

*To the Editor of the Medical Gazette.*

SIR,

I was requested in January last to assist Mr. Christopher Hunter, of Downham in Norfolk, in the application of a ligature on the carotid artery; and I send you the particulars of the case (should you think them worthy of notice) for insertion in the pages of your valuable journal.—I am, sir,

Your obedient servant,

HENRY CHARLES JOHNSON.

6, Saville Row,  
March 22, 1842.

John Chase, æt. 29, residing at Lynn, in Norfolk, a stout, short-necked, muscular man, by trade a fisherman, discovered about ten days before Christmas last a small swelling on the right side of the neck, immediately below the angle of the jaw. The swelling gradually increased in size from the time it first attracted his attention. He had very frequently been engaged in pugilistic encounters, but never remembered having received a blow or injury which might in any way account for the existence of the swelling. Soon after Christmas he placed himself under the care of Mr. Hunter, and on the 22nd of January, 1842, the following was his condition. There was general enlargement of the right side of the neck, extending from the angle of the jaw towards the clavicle. No one portion of the enlargement of the neck was more prominent than another, but by carefully watching the part a distinct pulsation could be perceived. On examination by the hand, a tumor, of the size of a small egg, could easily be detected, situated at about the level of the thyroid cartilage, and extending inferiorly to within an inch and a half of the clavicle. The sterno-cleido-mastoideus muscle was stretched over it, and appeared to flatten its surface. Pulsation in the tumor, when examined from before or laterally, was very distinct, and pressure sensibly diminished its volume. On withdrawing the pressure the tumor assumed its former dimensions. Any interruption to the flow of blood through the trunk of the carotid artery below the tumor, suspended the pulsation in the tumor itself, rendering

it flaccid, and less perceptible to the touch. The patient did not complain of any inconvenience from the existence of the disease, and considered himself in perfect health.

The nature of the tumor being satisfactorily determined, Mr. Hunter proceeded to apply a ligature on the carotid artery, between the tumor and the arteria innominata. The patient was placed on a table, lying on his back, with a pillow under the shoulders, and the head inclined rather to the left side. An incision of three inches in length was made in the direction of the inner border of the sterno-cleido-mastoideus muscle, but rather nearer the median line of the body than the edge of the muscle itself. The incision extended quite to the lower part of the tumor, and from thence downwards to the upper border of the sternum. The skin, platysma, and fascia, being divided, several small veins crossed the direction of the incision; some were divided, and one of larger size than the rest was drawn to the outer edge of the wound, and the dissection then continued. The hæmorrhage was but slight. The sternal attachment of the sterno-cleido-mastoideus was separated from the bone, and a director placed beneath the outer margins of the sterno-thyroid and sterno-hyoid muscles, the fibres of which were divided in a transverse direction. The nervus descendens now did not appear in the dissection, being distributed to the muscles above the point of their division by the knife. The sheath of the vessels was thus fully exposed; and by means of a scalpel and forceps the artery was partially denuded, but separated as little as possible from the surrounding parts. A curved steel aneurism needle, armed with a ligature, was introduced beneath the vessel, from without inwards. The ligature when raised completely commanded the pulsation in the tumor. It was firmly tied, one end being divided close to the knot, the other remaining in the wound. A small strip of lint was placed in contact with the ligature, so as to allow a free exit for the escape of matter, and some adhesive straps were employed to keep the edges of the wound in contact. The artery at the point at which the ligature was applied was perfectly healthy. There was no difficulty with regard to the internal

jugular vein, during the operation, as it did not in any way interfere with the dissection. The artery, however, was at a great depth, and it was necessary to employ metal retractors to keep open the edges of the wound. The distance between the arteria innominata and the ligature could not have been more than an inch and a half.

22nd, vespere.—Slight bleeding from the wound; not much more than to wet the dressings. Complains of uneasy sensation about the epigastrium, approaching spasm in its character.

Pulse 80.—Very slight pulsation to be felt in the tumor.

23rd.—Slept but little during the night.

Pulse 74.—Tongue moist. Still complains of the sensation about the epigastrium and region of the heart.

To have some cold tea, with dry toast, and jelly in small quantities.

The dressings partly changed.

24th.—Pulse 80. Tongue clean. Bowels not relieved since the operation. The pain in the epigastrium has abated, but not altogether subsided.

Magnes. sulphat.  $\mathfrak{zss}$ . statim.

Vespere.—Wound discharging freely.

Pulse 90.—Bowels not acted upon.

Hydr. Chloridi. gr. iv. statim; Haustus Aperiens post hor. quatuor.

25th.—Slight cough. No pain in epigastrium.

Pulse 74.—Bowels open. Tongue clean. Appetite good.

$\mathfrak{R}$  Oxymel Scillæ  $\mathfrak{zj}$ .; Syrupi Papaver.  $\mathfrak{zss}$ .; M. Capt. Coch. med. j. urgente tusse.

To have broth and dry toast.

27th.—Doing well. Wound healthy, and discharging freely.

29th.—Mutton chop daily.

February 2nd.—Wound much contracted in size. Ligature firmly fixed in the wound.

3rd.—Walked about the house for a short time to-day. Requires an occasional purgative.

9th.—Walked out of doors.

13th.—The ligature came away this morning, the 22d day after the operation. The wound healed a day or two afterwards.

March 15th.—The patient quite well. A small hard knot remains in the situation of the tumor, without any pul-

sation. No perceptible difference exists between the right and left side of the neck; but on the right side the temporal artery pulsates with more vigour than on the left.

# CASE OF SERIOUS AND ALARMING HÆMORRHAGE AFTER THE EXTRACTION OF A TOOTH.

By H. DAVENPORT, M.R.C.S.

Surgeon, Eltham, Kent.

[For the London Medical Gazette.]

ON Sunday, 27th February, 1842, about half-past seven, A.M. Mr. Phipps, jun. æt. 23, stout and healthy, called on me and requested that I would extract a molar tooth of the lower jaw, that had given him considerable pain for some weeks, which I did, the tooth coming away without any difficulty, and perfectly clean. He returned home a short distance to breakfast, and made a hearty meal. At four o'clock P.M. he called me in, and stated that hæmorrhage had come on about two hours after the extraction, and continued ever since. On examining the socket I found large clots of blood, which I removed, and immediately plugged it very tightly with lint dipped in a solution of alum and zinc, and placed a cork over the lint, pressing firmly into the socket, the upper jaw resting upon it. I called again in two hours: hæmorrhage going on as usual, rapidly. I removed the plugs and took a portion of fine wadding in small pieces dipped in the solution of alum and zinc, and gradually pressed it to the bottom of the socket, thinking though I had plugged it tightly before, I had not pressed on the extreme point of the socket whence the hæmorrhage proceeded, and placed the cork on it as before. I saw him again in two hours; no alteration; I removed the cork, and made firm pressure with my finger and thumb on the sides and top of the socket for half an hour, which appeared to arrest it for a short time: when the finger and thumb were removed it returned again. I again removed the plug, and dipped some lint in a solution of kino and a strong solution of alum, and pressed it firmly in the socket as before, and directed him to hold a

strong solution of alum constantly in his mouth. At ten o'clock it apparently ceased, the solution coming away from his mouth colourless. I then left him.

Feb. 28.—Visited him again this morning between seven and eight o'clock, and was informed that the bleeding returned shortly after I left, and his father then tried a remedy of his own, by filling the cavity with resin very finely powdered, and pressing it down with lint; it then ceased for two hours and a half, when, in the act of coughing, it came on as bad as ever, and continued till morning. On examining the cavity, I found large clots almost as solid as liver formed round the plug, and nearly filling the mouth, and was surprised that such firm coagula did not check the hæmorrhage: the blood still flowed from his mouth. I again removed the plug and coagula, and thinking that burnt alum deprived of its water of crystallization might have a better effect, I tried it, but without much apparent benefit. At twelve o'clock no change for the better. I now passed a stick of caustic finely pointed to the bottom of the socket, and against the sides, and plugged it as before. Saw him again at three o'clock: profuse hæmorrhage still going on, which now became alarming, and his friends anxious from the large quantity of blood he had lost, which could not be less than seven pints. At six o'clock I tried a new preparation, which Mr. Hill, of Guy's Hospital, recommends in his work on Cupping as very effectual in stopping hæmorrhage, called *licopodium*, or devil's puff; but it had no effect in this case. Half-past seven, blood still flowing, though the pulse had not given way a great deal: countenance anxious, and complained of lassitude and debility. The case now became very serious, and I felt convinced in my own mind that unless we could check the hæmorrhage, in a few hours it would prove fatal, and suggested to his father the propriety of having another opinion, which was immediately complied with, and a carriage was sent to town to fetch Mr. Thomson, of Grosvenor Street, surgeon dentist, being informed he had once checked hæmorrhage of some hours' standing in a similar case. Eight o'clock, thirty-four hours from the commencement of the hæmorrhage,

when carefully watching him, and thinking I would apply the actual cautery, he suddenly became very sick and faint, and brought up a considerable quantity of clotted blood, from which time the hæmorrhage ceased, and did not again return, leaving him very weak and low, having lost between nine and ten pints of blood as nearly as I could judge. Mr. Thomson arrived at half-past eleven. The hæmorrhage had ceased for three hours, so that the patient was not disturbed.

I forward this case to shew the difficulty that sometimes arises in checking hæmorrhage from a dental cavity, and if it had continued, as a last resource, I know of no other remedy than tying the carotid artery, which was once performed in a similar case by Sir B. Brodie, but did not succeed: but perhaps some of your correspondents may inform me of some remedy that might prove more effectual than any I have used in this case.

#### FACTS AND IMPRESSIONS ON MEDICAL SUBJECTS.

(For the *London Medical Gazette*.)

WE have room for a few more extracts from this volume, which may not be in the hands of all our readers. The first is of a better quality than the desultory passages we have before selected. The second is in the author's usual vein,—a case,—which we dare say is meant to convey a great deal, but unluckily the only thing it clearly displays is the cloven foot of professional heresy. Oh! if those who favour medical innovations could see themselves reflected in the form and colours in which steady orthodox practitioners see them, how would they shrink from their mirror'd horns and tail, and sable complexion! how quickly would they repudiate their errors! And indeed we are happy to say they are in truth constantly doing so. Thus the late Sir ———, who was much indebted to Dr. S., the colleague of the late Dr. Harrison, for attendance in his family, told Dr. S. that he was sorry to be compelled to take the step, but he was obliged to declare to him, that for the future they must be strangers, both in public and in private: however, he added, to soften the blow, that he would occasionally look in upon him. Thus, most properly,

did Sir ——— give up his deliberate opinions and his friend, avowedly on representations made to him by his own colleagues, as to the odiousness of the system he had temporarily favoured. In like manner Dr. ——— expressed to the same party, who was attending a child of his, the pain which he continually suffered from the remarks of his profession on the subject, and finally turned him off. The late Sir Astley Cooper again, probably the ablest surgeon, take him all in all, the world has bred, but not less able as a shrewd judge of the world, was told by Dr. ———, a living London physician, eminent for his general talent and scientific character, as well as for his professional knowledge and judgment, that having been sent for into Kent, to see a patient, the apothecary begged the doctor would look at another, the subject of some nervous disorder, who, among various odd symptoms, could only discern things properly when held to her upside down; and the doctor accordingly saw her read inverted books: "My dear sir," said Sir Astley, "that is very curious, but you know you must not tell it." Here are useful lessons! We know captious people say, "how is knowledge to be improved, if we are to suppress every thing new?" To this we might reply boldly, what occasion, pray, is there for the improvement of knowledge? would you excel all that has been? would you be *felicior Augusto, melior Trajano*? a more prosperous surgeon than Cooper, a better physician than Baillie? And pray what did Harvey get by discovering the circulation of the blood? why, he lost his practice: or what did Galileo do, when he found that proving the Copernican theory true, threatened to bring him to the stake? Most properly, he gave up the discovery, and allowed the earth to remain theoretically stationary. And pray did this prevent the truth, which he abandoned, becoming established? Quite the reverse: it is for the interest of truth itself to suppress it: like the chamomile, the more it is trodden on, the faster it grows, or

"*Duris ut ilex tonsa bipennibus,  
Per damona, per cœdes, ab ipso  
Ducit opes animumque ferro.*"

It is therefore right not to foster or promulgate new truths for our interests sake; and most important to repress

and crush others who advocate them, partly for the same reason, partly as experience shews this to be the condition under which knowledge has always advanced.

*Of amputation of the breast.*—This operation is now much less frequently resorted to than formerly. The grounds upon which it is to be recommended have shifted in the advance of knowledge, and the opinions of the profession have not yet had time to settle on their new foundations. Perhaps the following observations, by one who has had fair opportunities of studying the subject, may on this account prove of present use.

Towards thirty years ago I was taught to look at this operation exclusively in reference to cancer, and to consider cases of cancer of the breast as referable to two classes, one in which the disease might be removed by an operation with a tolerable chance of its not reappearing; the other in which, either from the advanced stage of the cancer, it was too late, or from the disease co-existing in other parts, it was impossible, to contemplate its extirpation. So a small scirrhus lump in the breast, with no enlargement of the axillary glands, was a proper case to operate on; and a very large tumor, or the tumor being ulcerated, or the lymphatic glands being affected to an extent not admitting their simultaneous removal—these were conditions that contravened the operation. The breast was to be removed only when the whole extent of the existing disease could be certainly removed with it. And the aim of the operation was permanently to eradicate the cancer, and the disposition to cancer. It was, indeed, well known that the disease would often reappear, when all the circumstances favourable to the operation had been present; but it was confidently believed that a great many patients on the other hand were permanently cured by the operation.

The latter opinion was erroneous, and sprung from the imperfect diagnosis of cancer of the breast, which these obtained. Many tumors of the breast were considered to be scirrhus, which were of another nature, and these swelled the list of cases represented as permanently cured by the operation.

Now that scirrhus is positively iden-

tifiable, and need not be confounded with any other disease, experience tells us that the complaint recurs in ninety-nine cases out of a hundred; that it commonly reappears in from half a year to two years after the operation; that occasionally, but most rarely, its reappearance is put off for several years; and that in several cases, when let alone, the disease is very slow in its progress, and till the last mild in its symptoms.

Under these circumstances, some surgeons hesitate to recommend the operation in any case of scirrhus; as there is a moral certainty the disease will come back; a great probability that it will come back very shortly; and no evidence, as it is assumed, that the operation has the power of at all prolonging the patient's life.

My own opinions do not go so far as this. There are many cases in which I think the removal of a diseased breast the most judicious practice. What these are I will endeavour to specify. They are of two kinds—certain scirrhus tumors, and certain other tumors of different character.

1. Suppose a scirrhus of the breast, the tumor unadherent to the pectoral muscle, the axillary glands slightly if at all affected, occurring in a patient whose general appearance and whose bodily feelings argue strength of constitution, in whom there is no suspicion of the disease having yet attacked other organs, while in the breast it is now beginning to advance, the tumor being painful and sensibly enlarging; in such a case I think the patient would decide wisely in submitting to the operation.

Because, in this form of the disease, the pain to be expected, in its natural progress, is extremely severe. Because, the breast being removed, the subsequent outward spread of the disease might be confined to the axillary glands, where it is much less painful. Because, on the other hand, the disposition to scirrhus growth might for a long time be rife about the breast alone, and show itself only in the return of one or two tumors in the same pectoral region, which might be again removed. Because in either case there would be one, in the latter case two periods of indefinite duration of restored health and hope. Because it is always possible that any single

case may prove the fortunate one, in which the disease is slow in reappearing.

Nor should I be deterred from recommending this course, by the fact of the tumor having begun to ulcerate; the other favourable conditions being present. Nor, on the other hand, if the scirrhus tumor did but occupy a quarter or a third of a full voluminous breast, would I amputate the whole of the breast, but take away the portion only including the manifest disease. Both operations I have performed, and have been satisfied with the result.

Of the arguments advanced above for amputation of the breast in the class of cases specified, there is but one towards which the experience of every surgeon will not furnish him with instances; and that is the contemplation of a second operation. The following cases are given to exemplify the occasional utility of this practice, and they are not the only favourable examples I have met with.

In March 1835, with the assistance of Mr. Sutherland, of Caroline Street, Bedford Square, I removed a lady's breast for scirrhus. She was unmarried, aged about 50, thin and spare in habit: the entire gland was indurated. It formed a small tumor only. The integuments were very lax, the tumor unadherent. In July 1836, I again saw this lady; there was a firm, elastic, cartilage-like tumor, of an oblong form, not so large as the original tumor, involving part of the cicatrix. This I removed by a second operation. Mr. Sutherland, two months ago, assured me that this lady had remained perfectly well since. (March, 1842.)

In May 1835, Mr. Stanley removed the right breast of Mrs. N. She was 67 years of age, had borne six children, and had been aware of the existence of a tumor of the breast for three years. The wound had healed favourably, and there was no tightness of, or traction on, the cicatrix: she was a person of a full habit, strong, and unbroken by years. In six months a new lump formed, extending to the upper part of the cicatrix; towards the summer of 1836 it had acquired the size of a small orange, when she consulted me, and I removed it. It proved a circumscribed tumor of the more succulent and softer form of scirrhus; in my experience that of rapidest growth. This patient I

saw during the present winter, and have several times before seen her since the second operation; once or twice there were threatenings, fulness and uneasiness about the neighbourhood of the cicatrix;—which dispersed on applying leeches. Now, and now only, the disease is certainly reappearing in the other breast. It is probable that, in these two cases, certain in the last, much suffering has been saved, and in all probability life prolonged, by the two operations.

Neither do I see any argument that can be sustained against the operation in the class of cases supposed. I have never lost a patient through the operation; neither, for many years that I have learnt to dress the wound lightly, and have allowed the patient in a few days to use the arm a little, have I known recovery from the operation protracted: nor do I believe that in any case the march of the disease has been precipitated by the operation. The only but most serious drawback against it is, then, the pain; if that could be avoided, or if the patient is of that firm nerve to bear it, there can surely be no doubt the patient will have gained by losing the tumor.

When the disease is advanced beyond a certain point, when other organs are affected, when the patient is worn in constitution, pale, feeble, timid,—in these cases the operation cannot be recommended. In this unpromising class I include, of course, cases where the disease, as yet confined to the pectoral region, has sensibly produced a change in the cellular and adipose tissue around the indurated breast.

2. The other class of cases, in which amputation of the breast is advisable, comprises great enlargements of the breast, combining induration and a cystiform character, of which one remarkable instance is related in Mr. Mayo's Pathology; likewise some advanced cases of the sero-cystic disease of the breast described by Sir Benjamin Brodie; likewise, large moveable tumors, not malignant, nor adherent, but painful and increasing, situated in the pectoral region, but of uncertain relation to the gland, of which an instance again is given by Mr. Mayo: finally, such cases as the following:—

A healthy-looking young woman, between 20 and 30, for some time had observed a swelling, with occasional

uneasiness, in the left breast. During the last few months it had increased rapidly, and had become extremely painful. The breast was very large; upon the inner aspect it had a healthy appearance; in front and without several large veins showed themselves through the integuments, and the gland of the breast felt much enlarged, firm, elastic, and as if it contained fluid at parts. The skin was nowhere tensely adherent to the tumor; and the tumor moved freely on the pectoral muscle; and the axillary glands were not affected. On puncturing the breast at two parts, two cysts were opened, from which several ounces of turbid brown fluid were evacuated, leaving the tumor not much diminished in size, and not altered in character. I then amputated it. The patient speedily recovered, and continued well at the expiration of a year, since when, now two years, I have heard no more of her. The tumor, when cut through, looked like fungoid disease or medullary sarcoma, and, in the turbid fluid expressed from it, Mr. Tomes saw the larger oval corpuscles of a granular appearance, common in that disease, to which family, no doubt, such tumors belong. In a more systematic notice of this subject, the case here detailed would have fallen under the general head of malignant disease; but from the uncertainty of the diagnosis, practically, it is as well to place it apart from ordinary scirrhus of the breast.

*Caries of the spine.*—Some years ago, the late Mr. Robinson, of Weymouth street, requested I would look at a lad, about 13 years of age, a young relative of his, who ailed something, but they could not make out what. After cross-questioning him, stripping him, and looking him over carefully, I made out these symptoms—that he had occasionally pain extending along the side, in the direction of the middle ribs; that his hands and arms would at times go to sleep when he rested upon them at his desk, and that an obscure sense of inward soreness could be produced, by tapping the lowest cervical and upper dorsal spines. I accordingly made an issue in this region, recommending that the boy should remain at home and be kept quiet, and lie down a good deal. After some weeks he became well.

It must have been a year to a year

and a half before I again heard of him. He had been at school, enjoyed his health for a time; then he again fell out of condition. His legs seemed to fail him; sometimes they would catch and cross, and throw him down. He had indeed now manifest spinal disease: there was an evident projection of three spinous processes at the lower part of the back. Accordingly I recommended that he should be kept constantly recumbent, and an issue made on one side of the projecting vertebræ. This treatment was pursued for two or three months; and he was taken to the sea-side, and every care observed; but he got worse, and the paraplegia increased. Then Sir Astley Cooper saw the lad with me, and the usual routine of spine treatment was gone through: still the boy got worse, when Mr. Robinson said to Sir Astley Cooper and myself, "The boy is certainly worse; will you object to Dr. Harrison's plan being tried, as yours has unfortunately failed?" Of course we assented, and the boy was placed under the care of Dr. Serny, Dr. Harrison's successor. It was not long before he began to improve, and, in fine, in two to three years he was perfectly restored. Every one knows now that Dr. Serny's plan consists in keeping the patient in the recumbent posture, taking off all strain from the spine, by lacing to the body two shields—one before and the other behind; and making systematic extension of, and pressure on, the spine. Dr. Serny very liberally shows his apparatus to every one; and having seen the good results effected on the patient whose case I have given, I availed myself of Dr. Serny's politeness to look at several of his patients while under treatment. Their healthy cheerful look—the look of physical relief about them—so different from the usual worn and suffering look of spine patients, convinced me that Dr. Serny's plan is the proper one for caries of the back. Then I wondered how it was this plan had been so decried. The principal reason may have been this. Dr. Harrison used to talk utter nonsense about his practice. He said, I believe, that all spinal disease originated in displacement, and that by his plan the bones were forced back into their places. And it was perhaps but natural that those who heard that his practice was based upon facts so false

should have thought the practice must be good for nothing, or worse. But there is no reason why an ignorant person should not fall upon a good remedy; although, unluckily, his ignorance will lead him to apply it indiscriminately; and the failures thus arising from his ignorance tend materially to strengthen the first conceived prejudice against him. I repeat that it now appears to me certain, that, for caries of the back, absolute rest, with gradual extension, is the proper treatment. How desirable it is that this practice should be generally and systematically adopted! Even Mr. Verral's plan of prone support, which is an approach to it, in my own experience much exceeds our old methods in efficacy.

---

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

---

*A Manual of General Therapeutics, with Rules for Prescribing, and a copious collection of Formulæ.* By D. SPILLAN, M.D. Fellow of the King and Queen's College of Physicians in Ireland. London, Renshaw, 1841. 8vo. pp. 458.

DR. SPILLAN, in his preface to the above work, after noting the distinction between *rational* and *empirical* practice, complains that the treatment of many of the diseases which fall under the cognizance of the physician cannot yet be styled rational. "We know," he observes, "the value of mercury in the treatment of syphilis; of tartar emetic in pneumonia; and of colchicum in gout; such knowledge, however, is confessedly empirical. We cannot connect the action of these substances with the lesion to the removal of which they are adapted. We know from experience that they are useful; we do not know why?" It is, therefore, in order to fill in some measure this hiatus in medical knowledge, that the present treatise is intended; the author's aim being to "establish the science of therapeutics on rational grounds, as far as that can be accomplished in the present state of medical science;" "to ascertain the laws to be followed in the employment of those methods of

cure which have been dictated by reason, deduced from the principles of physiology and pathology, or sanctioned by judicious and well-trained experience;" and to enable the physician "to justify the exhibition of the remedies which he employs, by reference to their primary action, and to the organic changes that they are calculated to produce."

Although we cannot say that Dr. Spillan has done much towards the accomplishment of these high objects, yet we are bound to add that the fault is in the subject, more than in the author. The mortifying truth is, that we cannot yet (in by far the majority of cases) trace any connection between the nature of the remedy and its action; we can produce a definite effect by certain means, but cannot tell why. Our inquiries must always terminate in some general fact, of which no account can be given, but that such is the constitution of nature; and attempts to pursue our inquiries farther can but lead to confusion, by blending truth with conjecture; only overlaying it with a mist of apparent explanations that fill the ear, but teach nothing to the understanding; and that are perpetually shifting and changing according to the popular theory of the day. The surgical author of the last century ordered a poultice in order to relax the over-extended fibre, soothe the enraged spirits, and qualify the orgasmus therein stirred up." The modern orders his water-dressing, in order to "allay a sense of irritation in the organic nerves." What do we learn more from these theories, than the fact that a poultice is good for a phlegmon?

Yet a very useful work may be made by gathering together what is really known of the action of medicines on the body, both in health and disease, and of the rules for their administration, which have been collected by the general observation of physicians up to the present time: and Dr. Spillan's work will be found to contain many useful practical maxims, collected from sound modern authorities. The fifth chapter, in particular, contains in forty pages a most judicious summary of whatever has been really ascertained by experiment concerning the *modus operandi* of medicines; their absorption into the blood, their deposition in the various organs, and their elimina-

tion by the secretions. This chapter is condensed from Dr. Herr's "*Theorie der Arzneiwirkungen*." If we are disposed to find fault, we might allude to the occasional careless composition and inaccuracies to be met with in the latter half of the book; the too copious extracts from Barbier's work on Therapeutics; and the want of a table of contents and running title. In a work of this kind, an easy means of reference to particular passages is above all things desirable; and the author should consult the convenience and comfort of his readers, as well as provide for their instruction.

*Outlines of Human Osteology.* By F. O. WARD. London: Henry Renshaw. 1841. 16mo. pp 528.

WE are glad to announce the completion of this work, the first part of which was published three years ago, because it is seldom that we meet with a treatise, on so old a subject as anatomy, that displays so much freshness of conception and original research, and, at the same time, such constant reference to the opinions and descriptions of others. In fact, every page bears ample testimony to the account which the preface gives, of the manner in which the work was composed.

"A minute description of the human skeleton," says Mr. Ward, "was first written, without reference to any other authority than that of nature. This description was subsequently enlarged and improved by comparison with the works of Cloquet, Cruveilhier, and other standard authors. Whatever contradictory statements came under my notice in the course of this comparison, were noted down, and made the subject of careful research in several extensive anatomical collections, particularly in that of M. Alexandre, which afforded me an opportunity of examining nearly 200 specimens of each bone. The results thus obtained were embodied in the work, and the whole subjected to a close and scrupulous revision."

The descriptions throughout are most minute and clear; the arrangement and subdivisions are methodical and sufficient, without being too minute and trifling; and, what is not of least importance, the printing is executed in such a manner that the divisions readily strike the eye. More-

over, the mere dry descriptions, of which the bulk of the work necessarily consists, are most agreeably diversified with physiological explanations of the construction and mechanism of the skeleton, especially of the mechanism of the carpus and tarsus, of the solutions of the radius and ulna, and of the obliquity of the neck of the femur, on all of which points we meet with the marks of original and ingenious research. Witness the following extract respecting the strength of bone:—

“A cubic inch of cancellous tissue was cut from the centre of the external condyle of an adult macerated femur, and subjected to gradually-increasing pressure, with the following results. It sustained four hundred weight, without sensible alteration; sank a little upon one side on the addition of the next half-hundred weight; and continued to yield upon any increase of pressure; so that when the weight amounted to 6 cwt. its height was reduced to half an inch. The reduction, however, took place entirely at the expense of the upper portion of the cube; its lower moiety, which presented a much closer texture, bore the whole pressure of 6 cwt. without visible alteration. The weight of the cube submitted to this trial was 54 grains troy. It was placed during the experiment in the natural position, with its principal fibres upright. The side on which the cube first gave way corresponded to the outer and posterior part of the condyle; and its structure was here evidently looser and more fragile than on the side which in the natural position had laid nearest to the axis of the bone. In Mr. Rennie's experiments on the strength of woods, a cubic inch of solid elm was crushed by 1284 lbs. avoirdupois—about  $2\frac{1}{2}$  times the weight beneath which the cube of reticular tissue began to yield. This comparison may assist the reader in forming a just estimate of the strength of reticulated tissue.”

We can most conscientiously recommend the work to the younger student, who is beginning the study of anatomy, as well as the more advanced, who wishes to add correctness and precision to the knowledge he has already obtained.

## MEDICAL GAZETTE.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

### ALLEGED DEFECTS OF VACCINATION.

IN our last number we laid before our readers the Report of the National Vaccine Establishment for the current year. Meagre as these documents have been on several previous occasions, that which the Board have recently put forth exceeds them all in scantiness of information. It tells us, in fact, nothing more than the number of thousands of armed ivory points which the Board have issued during the past year. On the extent to which, in this period, small-pox has prevailed in the provinces, as compared with the metropolis, or with former years—on the general feeling of the public in regard to the amount of security which vaccination gives—on the number of well-authenticated cases of small-pox succeeding to vaccination which have been reported to the Board, and on the character of such cases—on the working of the new Vaccination Act;—in a word, on the many interesting questions which the subject of national vaccination presents to the mind of an intelligent inquirer at the present moment, the Report of the National Vaccine Board says literally nothing, if we except the announcement, that provincial vaccinators are unable to keep up their own stock of lymph. We marvel at this literary parsimony, because it cannot be that they have nothing to tell us. The National Vaccine Establishment have correspondents and honorary vaccinators scattered over the whole country, and much valuable information must

of necessity be obtainable from their communications. Neither can it be said that the diffusion of such information is uncalled for, and would, if produced, be valueless. There is now lying before us a work published within the last month\*, in which the defects of vaccination are set forth very prominently; and, from a passage in the work, it appears that the Board were early made acquainted with the intention of the author to renew his attack upon vaccination. We are far from intending to insinuate that it is any part of the duty of the National Vaccine Board to refute the sophistries of Mr. Brown; but it surely would not be inconsistent with the dignity of that Board to put into the hands of others the weapons by which such attacks on the credit of vaccination may be successfully resisted. So important does it seem to us, that a volume bearing such a title as that we have now quoted, should be noticed, and its errors exposed and refuted, that we shall, in our criticism on this work, depart a little from the mode usually followed on like occasions. We shall take the present opportunity not merely of explaining to our readers the arguments which Mr. Brown puts forth in support of his position, but we shall narrate circumstances which will enable them to judge how far Mr. Brown is competent or not to adjudicate on the merits of vaccination.

Mr. Brown, who now steps forward as the uncompromising opponent of vaccination, is the same person who, in 1809, while a practising surgeon at Musselburgh (a fishing village near Edinburgh), headed the first regular attack on the Jennerian discovery: for the absurdities of Dr. Moseley were too

glaring and too contemptible to merit notice. The statements of Mr. Brown, however, had a certain foundation in nature. His inferences were overstrained, but his facts were, in many instances, correctly stated. Notwithstanding his objections to vaccination, we learn that Mr. Brown continued for many years, subsequent to 1809, to practise it. Since the year 1835, when he gave up practice, he has continued firm to his original text—the defects of vaccination, and now openly avows his belief (page 12), “that the practice of vaccination is full of inconsistencies, contradictions, and imperfections; and, unless it be improved, is unworthy of further confidence.” Mr. Brown is well-stricken in years. He was in practice 52 years ago, and, between the years 1790 and 1800, had inoculated about 1200 cases. He retains a strong predilection in favour of inoculation, and would fain see the world revert to that practice. But it is time that we lay before our readers a sketch of those alleged defects of vaccination which seem so formidable in the eyes of Mr. Brown, and which induce him to recommend a return to the practice of inoculation.

The great, and indeed we may say the sole, defect of vaccination in the eyes of Mr. Brown is, that the security afforded by it is imperfect and temporary. To be worth any thing, according to Mr. Brown, the preservative power must be absolute and permanent. He will admit of no compromise. *Aut Cæsar aut nullus* is his maxim. Con-vict vaccination of failing in certain cases to afford this absolute and permanent security, and forthwith it should be abandoned. Mr. Brown enters into some details concerning the proportion of the vaccinated who, in after life, yield to the small-pox contagion, and he comes to the conclusion (p. 73) that “above one-half of the vaccinated

\* An Investigation of the present Unsatisfactory and Defective State of Vaccination, and the several Expedients proposed for removing the now-acknowledged Defects of the Jennerian Practice. By Thomas Brown. 1842.

cases have already so yielded." He then adds, "when we consider that vaccination has not yet been proved by above one-half of the period of human life, it does not seem asserting too much to say, that unless some expedient can be contrived to render the anti-variola powers more complete, the whole, or nearly so, of the vaccinated cases may suffer an attack of small-pox, and this not of the safest and mildest, but of the most severe and fatal nature."

This, to be sure, is a sad picture of vaccine defalcation, and, if it were a faithful picture, we suspect that the eloquence of Mr. Brown would not have been needed to uproot the practice of vaccination. The common sense of mankind would have taught them the futility of the Jennerian practice, which, under such circumstances, would either have silently languished, or been authoritatively put down. The force of this argument is wholly lost upon Mr. Brown. He acknowledges, with some surprise to be sure (page 72), that the withdrawal of public confidence in vaccination "has been delayed longer than he expected," but he does not, or will not, see that this very delay should have suggested doubts as to the correctness of his data. Ample time has been given. Forty-four years have elapsed since the discovery of vaccination. Forty years after its general adoption in this country, the united voice of the empire, in Parliament assembled, declared itself so perfectly satisfied with the amount of the security that vaccination gives, that the inoculation of small-pox was declared illegal, the practice of vaccination throughout England and Ireland was placed under the direct control of the Government, and a tax levied for its support and encouragement. One would have imagined that this must have opened the eyes of the most bigoted. No! Mr. Brown declares

the Vaccination Extension Bill of 1840 to be "a disgrace to the profession in all its features." He still adheres to his early impressions. Vaccination is not what it was first represented to be—a complete, certain, uniform, unvarying, permanent security against small-pox. It has not banished small-pox from among us, as we were fondly told it would undoubtedly do; therefore, *delenda est Carthago*:—Vaccination must be abolished, and inoculation again encouraged.

Mr. Brown's error consists in his fixed determination to view only one side of the picture. He is an advocate pleading in the cause, "Inoculation *versus* Vaccination"—a prophet anxious to make good his own predictions, but he is no judge balancing nicely the arguments *pro* and *con.*, and arriving at length at a carefully drawn and practical conclusion.

That the merits of vaccination were largely overrated at the outset of its career, by Jenner and his followers, must be admitted. They undertook to prognosticate what would be the effects of vaccination under every possible contingency of age, time, climate, and constitution. They boldly announced its power of banishing small-pox from the earth, before it had even reached tropical countries, and ere a single black child had been vaccinated. They spoke of absolute and permanent security extending through the whole period of man's life, before vaccination had been known two years. This confidence of tone and manner had a wonderful influence on the early history of vaccination. It gave a powerful stimulus to the exertions of its friends and supporters, and materially assisted in fostering that rapid growth in public esteem, which is the great feature distinguishing vaccination from inoculation. How far its career would have been affected by a more cautious and

philosophical announcement of probable results is a mere matter of conjecture. We apprehend that, in such a case, its early progress in public favour would have been much slower; but still, like inoculation, it would have advanced steadily, until, at the present period, the actual condition of the world with reference to vaccination would have been much as we actually find it.

That absolute and permanent security, for the possession of which the early vaccinators so loudly vaunted vaccination, and for the want of which Mr. Brown now as loudly accuses it, is not expected by the world at large. They know too well the admixture of good and evil in the affairs of the world to anticipate such a result. They know that the storm and the lightning which clear the air root up forests and engulf ships. To come nearer home, they know that an income tax, with all its manifold public advantages, must be productive of partial injury and local dissatisfaction; but on a balance of the account, the world is satisfied with the quantum of benefit still standing to the credit of vaccination. One swallow does not make a summer; neither do one, two, nor three hundred cases of small-pox succeeding to vaccination withdraw from the public mind its confidence in vaccination, provided that one, two, or more thousand remain secure, and the total amount of deaths and injury to eye and constitution inflicted by small-pox falls short of what it did in the days of our fathers. We recommend to Mr. Brown the study of statistics. The cleverest reasoning fades before the dispassionate results of figures in long columns. Small-pox exists, but it exists shorn of many of its worst features; and when it does invade the vaccinated, it is no longer the direful disease which our ancestors knew, and so justly dreaded.

While we thus blame Mr. Brown for the one-sided picture of vaccination which he gives, we do not on the other conceal from ourselves the injury done to a good cause by persisting in those confident announcements of the complete and permanent security afforded by it, which we still occasionally meet with in high quarters. It is quite idle at this time of day to indulge in such vain boastings. Small-pox occurring after vaccination has its pathological characters as clearly defined as small-pox in the unprotected. We hope, therefore, that in future it will not be thought necessary for the upholding of vaccination to over-estimate its merit, or to overlook its defects.

In the observations now made we have reasoned with Mr. Brown more calmly than his own tone would strictly warrant us in doing. We have done so because we would not detract from the merit which really belongs to him. Mr. Brown was the first who publicly announced that the brilliant anticipations of Jenner were too highly coloured, and that a certain proportion of the vaccinated would imbibe the contagion of small-pox in after-life. Had he remained satisfied with this advance in vaccine pathology, still more if he had set himself diligently to investigate the actual amount of vaccine imperfection, he would have earned for himself an enviable notoriety. By overstating his case—by using unnecessary violence of language—by arguing in the worst spirit of prejudice—he has forfeited all claim to the character of a pathologist, and must rank with the Mosleys and Birches of the profession. We must treat our readers with some choice specimens of Mr. Brown's efforts as an improver of medical science.

At page 4 he tells us, "that if varicellous inoculation had been made imperative upon the whole population, not only would the present dilemma have been avoided, but the only probable

and possible way of resisting the ravages, and even extinguishing the existence, of contagious small-pox, would have been the result." Small-pox extinguished by inoculation! As the sentence stands it is absolute nonsense. Perhaps, the author meant to say that inoculation universally practised would have banished epidemic visitations of small-pox. If so, he took a strange way of enunciating his proposition. But how this principle of universal and imperative inoculation could have been carried out puzzles us, for we learn, at page 60, that "if inoculation is performed on the young, enfeebled, and exhausted, the disease will be uniformly either severe, dangerous, or fatal."

Mr. Brown's practical hints concerning inoculation, and still more concerning vaccination, are too singular to be passed over in silence. He says, that while all measures are to be pursued calculated to render variolous inoculation mild, "the opposite plan should be adopted in regard to vaccination, and every means used to make the phenomena of the vaccinated spot as severe as possible." And how do our readers suppose that this is to be effected? To secure this most important object, says Mr. Brown (at p. 61), the virus should be allowed to become a little dried or viscid upon the lancet before it is inserted in the arm! Besides which, the vaccinated spot should be kept hot, and a slight irritation excited by temporary pressure! Such is Mr. Brown's mode of improving the practice of vaccination.

Mr. Brown propounds, at page 63, the strange notion, "that cases of small-pox succeeding to vaccination have been in general confined to the lower classes of society." We feel satisfied that this is a complete error. The upper classes have always had their fair share of the defects as well as of the benefits of vaccination. We

notice this error of Mr. Brown's the more willingly, because he couples it with a recommendation in which we perfectly coincide. "Nothing can be a greater error," says he, "than the taking vaccinated children under ten years of age away from an epidemic small-pox, for, if they are to have it, they would then receive the contagion while the influence of the previous vaccination over the constitution is yet capable of mitigating the disease; whereas, later in life, when engaged in all the duties of social life, they may be attacked with small-pox, when the influence of the vaccine is either diminished or exhausted." The good sense of these few lines will atone for much of the accompanying absurdity.

Mr. Brown takes up in succession the several modes which have been proposed for improving the practice of vaccination, and fortifying the public mind in its behalf. It is hardly necessary to say that he finds fault with all of them. He begins with revaccination; but having made up his mind that primary vaccination, with its more decided results, affords only a partial, feeble, uncertain, and temporary security, it is hardly to be wondered at that revaccination, with its imperfect phenomena, should be declared "unworthy the confidence of any reasonable being." He proceeds to the consideration of retro-vaccination, or the method of increasing the intensity of the vaccine virus by passing it again through the body of the cow. This, in the onset, without any inquiry into the facts, Mr. Brown at once sets down "as the most unsatisfactory, unphilosophical, and unworthy expedient that could possibly be contrived, carrying inconsistency and contradiction on its very face. He has no hesitation in declaring, without laying claim to any experience in such an expedient, that it is only sporting with the good sense

and safety of the public, and will be found a ridiculous source of further confidence." These are hard words, but they are nothing more. M. Bousquet has a beautiful series of drawings, showing the difference in the progress of the long-humanized vaccine virus, and the same virus improved in its activity by the process of retro-vaccination. The results are very striking, and no one, who has enjoyed the advantages of study at the *École de Médecine*, but must be sensible of the remarkable power which this expedient possesses. All this, however, goes for nothing with Mr. Brown.

It fares no better with Mr. Ceely and the new variolo-vaccine virus; or rather, we ought to say, Mr. Brown is more inveterate against Mr. Ceely than even against Dr. Jenner. His experiments on the inoculation of cows with the matter of human variola, are declared to be unpleasant and disgusting, because he made use of the mucous membrane of the vulva, instead of the cellular membrane of the mamma! Mr. Brown however, in this part of the argument, impales himself on the horns of a dreadful dilemma. He declares that the variolo-vaccine, or the virus obtained by inoculating the cow with small-pox, can be none other than small-pox. Yet in the same breath he inveighs against the use of this very matter, and counsels a return to the practice of inoculation!

We have now completed the task which we proposed to ourselves. Our readers must by this time be sensible what sort of claim Mr. Brown can set up for the office of judge in the great question of vaccine security. We think that on this point there is not much room for difference of opinion. Mr. Brown has neither the temper nor the judgment that can qualify him for the task. He has not investigated the facts deeply, nor reasoned upon them with

fairness. His sole object is to disparage vaccination, and to cry up the advantages of inoculation. We do not join with those who take delight in depreciating a practice which saved the lives of our fathers and grandfathers, and which was steadily advancing in public favour when the practice of vaccination superseded it. We are fully sensible of the value of inoculation, and think Lady Mary Wortley Montagu a great benefactor to her country; but we are equally convinced that the practice of vaccination is a great improvement upon it, and that those who live in the nineteenth century have no cause to grumble at the alleged advantages which their predecessors of the eighteenth enjoyed in respect of an exemption from small-pox.

#### ON THE DIVISION OF MEDICAL LABOUR.

By ROBERT HULL, M.D.

(For the *London Medical Gazette*.)

##### *The Apothecary.*

WE live in days when the inconsistency of the human mind displays itself in flagrant characters. When men adopt the levelling principle, yet foster individual vanity—talk of republican equality, yet personally are as despotic as possible.

This has been enough manifested on the great and political arena. Reformers, deadly hostile to the aristocracy, yet aiming with eagerness at distinction: levellers, hating "the word gentleman," yet givers and takers of hereditary titles, with an hilarity truly ridiculous: the men of the people, the first moment is offered to them an everlasting separation from the people, jumping at the coronet or the sirship!

But this inconsistency is only apparent. Your levellers only level from above downward, down to themselves.

In our own profession, the reforming mania has been displayed; but the reformers are, almost all, men who are envious of superiors; who think them-

*Under the wider allusion to the  
"advancing which was..."*

selves worthy of the eminence, from whence they would detrude less worthy occupants—witlings who wonder at their professional obscurity; but content themselves with

“Full many a flower is born to blush unseen.”

When the hapless Sir H. C. lost a regal parturient, there was not in the empire a man-midwife who did not drop a hint that, had *he* been engaged, matters would have had a different termination. *He* had never lost a patient in midwifery! and the petty arena of every petty boaster resounded with lamentation that a man so “clever with women” as Mr. Dawson or Dobson, Jackson or Jobson, had been concealed in Cornwall or Devon, when he might have been salvatory to a princess and a nation. The court apothecary often knows more than the court physician. “Sir Jacob had the management; *but* her Royal Highness would have been alive to this day, had *I* been the adviser.”

There are, most certainly, in all human institutions, just enough of pegs of abuse whereon to hang vituperation. No clamour for reform but has some foundation; so imperfect is everything mundane. But the professional misery has been asserted, not by sufferers but by agitators. The Royal Colleges of Physicians, and of Surgeons, have had their share of virulent contumely. Yet we see men, who had been most opponent “on principle,” quickly swallowing the sop, and receiving the Fellowship or the Councilship, which a Roman sternness should have animated them to spurn.

The College of Physicians, as a licensing body, have been very much disliked. But surely the Government is as much at liberty to protect, as it chooses, the lieges from bad physicians as from bad lawyers or divines. The licences of the College have been demanded too sparingly rather than arbitrarily. How many men are practising in London without permission! what thousands in the provinces of Wales and England! the College quiet.

The pedants of that body, we are told, declined to give Jenner “their licence to practise in London; alleging, in excuse, his *proper* refusal to undergo examination in Greek and Latin.”

He who underrates those learned

tongues and the golden treasury they unlock, will provoke no antagonist to a reply. He who thinks that the discovery of the protective influence of cowpocks, *per se* and imperiously, gives a claim to the highest medical rank, forms a singular judgment of “the physician.”

The respect paid the profession in England is alone due to the high grounds successfully maintained, through successive reigns, by the College. Men of the old universities have boasted an education, in the same groves of Academus, with the peers and the aristocrats of the land. In active and after life they have maintained a proportional deference and position for themselves and their profession: and titles, opulence, and power, have been levelled in the republic of letters and of medical *lore*.

The dethronement, so to speak, of the Royal College, will be the signal of the degradation of our common profession.

The College may not have been, in former times, sufficiently pliable; it is so now. The modern admissions, without degrees academic, to the licence, places the College beyond cavil.

Individuals may still feel aggrieved; what mundane institution is perfect? Men of middle age, with foreign degrees, with general acquirements, may fancy there is humiliation, if they submit to an examination for the Collegiate licence. This would not prove the licence needless. The College aims at the practical physician; for him *alone* it was formed, for him exists. It is a thorough manly, English body.

Men may be very adept in the auxiliary sciences—great chemists, comparative anatomists, boundless natural historians—yet impotent in the art of healing.

Against this royal and other collegiate bodies, which constitute physicians, and, indeed, against the pure physician himself, the agitators have endeavoured to array the apothecaries. Persuading these gentlemen that, as they are equal in knowledge, they should not be inferior in rank. Too many have listened. Doubtless the apothecaries are a most worthy well-trained class. This is due to the calumniated Hall, which, whatever its errors, means well; and has, I verily

believe, done more good to the lieges than any other modern institution. And among these practisers, assuredly, many, very many, are to be found, who, for skill, philosophy, acquirements, are comparable with the most accomplished physicians.

Individuals will always exist essentially superior to their grades. Many private men are more strategic than commanders. Many clerks more jurisprudent than the heads of the firm. Many laymen more theologous than their parsons.

But, on the whole, society is best furnished with workmen, through varieties of labour, of rank, of pay.

The apothecaries, *on the whole*, cannot be supposed to equal the doctors of physic. They have not generally so complete an education. But if they had, the tumult, the hurry, the conflicting calls, the incessant occupation of practice, must prevent equal observation, equal study and improvement.

Of two persons, similarly endowed with capacity, with acquisitions, with ardour, one starting in practice as a physician, the other as an apothecary, the physician must get a-head, through pure advantage of leisure and repose.

The attempts of agitators to disrupt the harmony of these classes of practisers, should be opposed by all sober men. The apothecary should imitate the more ancient models; not the upstarts of reform. The physician should be scouted who invades the district of the apothecary. If he keep a surgery or a shop, he ought to be rumped without commiseration.

This segregation, so needful for the dignity and efficiency of the physician, must, I believe, depend solely on union of the body of physicians among themselves.

It is to be feared that the pharmaciens will not maintain the division of medical labour. I have known, on a large scale, the apothecaries sanctioning irregular practice in the physician, on the simple plea of interest. Loth, by refusal of a meeting, to let slip their patients; confessing their approval of our divisions, allowing that irregularity ought to be opposed, but lamenting, in the same breath, that they cannot afford to be high-minded. And this, not by the needy alone, but by opulent, carriage-keeping apothecaries, whose pusilla-

nimity keeps pace with their golden accumulation.

It would be easy to convince the money-loving pharmaceutic that his true policy is to stick to the rigid rules. He, by the usages of the whole country, may easily obtain his remuneration, by charging for his physic. Even the fee of the physician he greatly surpasses. His visits are numerous, close on each other; each succeeded by varying and costly drugs. What is his position if he defies the physician, drives him to his own resources, and makes him a rival, who should be a consultant? Will the patients of Mr. Higginbottom, or Mr. Pugsley, continue to pay their bills for physic, always deemed exorbitant, always suspected to be needless, if the physician near them should attend for a diminished fee, with little prescription of drugs? When, in fact, it will be cheapest to employ the graduate, and less nauseating. To this the apothecaries will drive the physicians, if the war continues. It is for the respectability of the graduates in England not to imitate the example of low fees, already set them in Dublin and Liverpool. It is for the interest of the apothecaries not to compel them; but to restore harmony—to cease from depreciation—to be friendly, if they are wise.

“σμερὰς ἀπ’ ἀρχῆς νεῖκος ἀνθρώποις μέγα γλῶσσ’ ἐκπαρξεί τοῦτο οἱ σοφοὶ ἐροῦν ἐξυλασθῆνται, μὴ φίλοις τεύχειν ἔινω.”

The race of pure apothecaries is nearly extinct; most of them are members of the College of Surgeons; all of them call themselves by this name. Be it so: this only renders more needful the distinct physicians. For what is the chance of maintaining the science of medicine, if it be left solely to general practitioners, who, however philosophic, are as busy, most of them, as the devil in a gale of wind? Where their leisure for original cogitation? where their midnight oil? Nor need these gentlemen give credit to the agitators that they are unduly disrespected. The members of the College of Surgeons, who are apothecaries, but keep no retail shop, are, as a body, too elevated in society to justify such sentiments. The major includes the minor. The surgeon swallows up the pharmacopole. Besides, as a body, they are richer than the graduates, over and over again. Let them not join in the

silly charge and calumny against physicians, that these

“ φρονόσι δήμου μείζον, ὄντες οὐδένας ;”

nor be gulled by the flattery of injudicious friends, who would persuade them that

“ οἱ δὲ αὐτῶν μυρῶ σοφώτεροι.  
εἰ τόλμα προσγένοιτο βούλησις θ' ἅμα.”

I believe that the Hall is quite disposed to protect them in their legal privileges, as well as the community to respect their great utility. But they must inform, they must complain, if they are injured or passed over.

At this moment lies before me a country paper, with the advertisement of a pedagogue turned apothecary. Let the gentlemen in his neighbourhood report him to the Hall! The whole affair is so barefaced, that they may reckon on instantaneous measures being taken by this beneficial body.

The practice of the druggists might easily be suppressed, at least restrained, if their complainants will but take the trouble to obtain the sufficient evidence.

The laws of this country are all in favour of the English apothecaries. Let them assert their claims. At present the laws know not any physician, who is not a licentiate of the Royal College. The College is passive, but the laws are express. The members of the Apothecaries' Hall are endowed with privileges superior to any other medicinal doctors. *Take the right of inspecting LUNATIC ASYLUMS.*

This appointment is expressly reserved for the members of our English institutions. The act of parliament (2 & 3 Geo. 4, c. 107) declares that the medical inspector must be a licentiate of the Royal College of Physicians, or of the Apothecaries' Hall, or a member of the College of Surgeons. This enactment would seem to have escaped the magistrates, at sessions, where they appoint their lunatic inspectors; and if the Colleges and Hall fail in their duty, which would seem to be the conveyance to the magistrates of counties and of towns, of the needful information, let the neglected apothecaries stir up their minds by way of remembrance. Let them demonstrate to the justices that, when they appoint any but *English* physicians, *English* surgeons, or *English* apothecaries—however intelligent the possessor of a Scotch or other degree may be—they violate

an act of parliament, which embraces in its provision every LUNATIC ASYLUM THROUGHOUT ENGLAND AND WALES.

## ROYAL MEDICAL & CHIRURGICAL SOCIETY.

March 22, 1842.

### THE PRESIDENT IN THE CHAIR.

*Cases of Perforation of the Stomach, of the Duodenum, and of the Bronchial Tube.*  
By WILLIAM BAINBRIDGE, Esq., Upper Tooting.

THE author observes that, as these cases are inevitably fatal, they present no feature of practical interest beyond the mere necessity of being acquainted with the circumstance of their occasional occurrence, so as to be able to distinguish the event, and give a correct prognosis.

Two cases are related of perforation of the stomach; the first occurred in a woman, æt. 60, of spare habits and sallow complexion, who, with the exception of vague symptoms of dyspepsia, felt pretty well until the evening of Sept. 26th, when, after having taken supper, she was seized with pain at the pit of the stomach, with fulness and oppression. These symptoms rapidly increased, attended with great anxiety and enormous distension of the belly. Active purgatives by the mouth, and turpentine clysters, were administered; the tube of the stomach-pump was also introduced to favour the escape of pus, but she sank on the 29th, apparently exhausted by a violent diarrhoea.

On examination after death, the whole of the peritoneum was found entirely red, with deposits of lymph and pus glueing together the intestines. The left lobe of the liver adhered to the anterior wall of the stomach: on separating this, there appeared a small circular orifice in the centre of the stomach, through which oozed its contents. In the anterior of the organ, corresponding to this opening, was a circular ulcer, with raised and indurated edges, surrounded with redness, but no softening of the membrane.

The second case was that of a healthy-looking girl, æt. 18, who was seized with a sense of sickness shortly after eating a hearty breakfast. Decided symptoms of peritoneal inflammation shortly supervened, such as vomiting, hiccup, tension, tenderness, and swelling of the abdomen; quick and thrilling pulse; cold and clammy perspiration: the vomiting continued incessant until her death, which took place in 24 hours. It is stated, that for two or three weeks previous to this attack, she had felt well, with the exception of a little pain at her epigastrium and between the shoulders.

**Examination after death.**—Effusion of serum into the peritoneal cavity; the intestines glued together by lymph and pus; a perforation, the size of a pea, in the anterior wall of the stomach; interiorly, corresponding to this, a round ulcer, with hardened and elevated edges.

In the two cases of perforation of the duodenum, the symptoms came on almost immediately after having taken a hearty meal; they were those of acute peritonitis.

On examination after death, besides effusion of serum into the peritoneal cavity, and deposits of lymph and pus, there was a rupture of the posterior part of the duodenum; in one instance to the extent of two, and in the other of three inches: the mucous membrane of this intestine was very soft, in one case a mere pulp.

One of these patients had previously suffered only from vague symptoms of dyspepsia, and the other was in perfect health up to the period of the attack.

The author observes that there must be a singular proneness in the upper part of the anterior wall of the stomach to this kind of ulceration, for in these two cases, and others which he has read, as well as in six specimens examined at Guy's Hospital, the ulcer was situated in very nearly the same spot.

With respect to the rupture of the duodenum, he refers to the work of Dr. Hodgkin on the Mucous Membranes, who states that the portion of the duodenum called the "pyloric valvule," is peculiarly prone to disease, and often very lacerable. In six cases of malignant scarlet fever which the author examined last year, he found this portion of the intestine intensely red, the remainder of the intestinal canal being healthy.

The symptoms after perforation the author states to be a severe pain at the epigastrium, or right hypochondrium, succeeded by the general symptoms of peritonitis. He, however, considers the extreme anxiety and distress of the patient's countenance as more pathognomonic of the occurrence than the vomiting or state of the pulse.

The President remarked on the peculiar character which the disease presented, in that the mucous membrane might be so considerably diseased without any signs of disorder, and that severe symptoms did not ensue till the peritoneal coat was destroyed. He observed that it seemed a general character of the diseases of certain mucous membranes that they were not accompanied by any very sensible signs of disorder, and detailed the case of a lad who was received into St. Thomas's Hospital after having swallowed a quantity of strong acid, and who was discharged ten days afterwards to all appearance well, but died three days

subsequently, and, as he supposed, from perforation of the peritoneum. He mentioned also two cases of rupture of the duodenum: one was in a young lady who had been previously in excellent health; but in raising her arm high up one day, felt something give way in the abdomen, and soon after died with a rupture of the duodenum, which in the neighbourhood was much softened. The other case was similar in its results, but differed in having been all along its course attended with acute dyspeptic symptoms.

Dr. Elliotson mentioned a case in which, contrary to the general course, the pain produced by perforation of the stomach ceased for several hours before death.

Mr. Bransby Cooper coincided with the President as to the peculiarity of the absence of symptoms of disease while the mucous membrane only was affected, and their severity when the peritoneal was attacked.

Mr. Probert related two cases in which death occurred in persons who to all appearance had shortly before been in perfect health, from perforating ulcers of the stomach. In one of these the ulceration of the stomach had evidently been for a long time plugged up by a portion of omentum, which adhered to it, and which had by some accidental circumstance given way, and permitted the escape of the contents.

Mr. Curling alluded to the occurrence of ulceration of the duodenum in connection with extensive burns, especially of the abdominal parietes, as having, perhaps, some relation to the cases mentioned in the paper of excessive redness of the mucous membrane of the duodenum in scarlet fever. In two cases that he had himself seen, death took place in consequence of the perforation of the duodenum by an ulcer after a burn, and he knew of a sufficient number of similar cases to render it certain that there was some connection between the injury and the intestinal affection.

Mr. Lloyd detailed three remarkable cases of abscesses communicating with the cavity of the stomach, and two in which foreign bodies in the appendix vermiformis had proved fatal by ulceration into the peritoneal cavity.

Dr. Addison pointed out the chronic character of the perforating ulcers as peculiarly worthy of notice. This was especially characterized by the thickening of the borders, which he had in one case seen amount to a full inch. Another remarkable fact was, that these ulcers did not give rise to hemorrhage. The disease seemed to be accompanied by such an effusion of albuminous substance in the neighbourhood of the ulcer, as was sufficient to close the blood-vessels which would otherwise be opened. The superficial ulceration of the stomach, on the contrary,

was frequently accompanied by hemorrhage. It was worthy of observation also that the disease occurred with peculiar frequency in young women, and he thought it might be connected with those signs of gastric disturbance to which it was well known they were subject when not regularly menstruating. He suggested it as a subject of interesting inquiry to determine whether there were any thing in the structure or the functions of the different parts of the stomach which would account for the fact that the lesser arch and its neighbourhood were almost invariably the seat of these perforating ulcers.

Mr. Paget mentioned four cases in which fatal hemorrhage had ensued from chronic ulcers of the stomach spreading to and opening large blood-vessels, and described the peculiar character by which this form of ulceration might always be distinguished from all others. Of five cases which he had recently examined, only one had occurred in a young female: and he said that the result of the comparison of nearly a hundred cases which had been collected by the professor of morbid anatomy at Vienna, had proved that, though the disease was more common in women than in men, and more common in young women than in those of other ages, the disproportion was not so great as was commonly supposed. He mentioned a case similar to Mr. Curling's, where fatal ulceration of the duodenum had taken place after a burn, and two others of chronic perforating ulcer of the duodenum; in one of which there was such a coincidence of hernia as led to the supposition that the patient was suffering from strangulation of the intestine.

Mr. Hawkins related a case in which he had found a well-marked cicatrix of an ulcer in the stomach.

Dr. Elliotson said that, according to his experience, the disease occurred almost exclusively in young women. He did not think there was any character by which its premonitory signs could be distinguished from those of ordinary chronic gastritis.

Dr. Kingston related a case of perforation by an ulcer of the duodenum which proved rapidly fatal.

Mr. Hilton asked if the cases of hemorrhage into the stomach, mentioned by Mr. Paget, were not the consequences of disease of the arteries themselves: such cases had occurred at Guy's Hospital. He could not understand how a large aperture could occur in the peritoneal coat unless the stomach had been previously adherent to the opposite surface of the peritoneum, and then suddenly separated from it; and that this did occur was rendered probable by the frequent existence of a spot on the peritoneum corresponding to the aperture in the stomach.

Mr. Paget said in the cases he had mentioned there was every character of chronic ulceration of the stomach spreading to the blood-vessels. He believed that the aperture in the peritoneum was always formed by sloughing. The ulcer spread slowly through the tissues till it came to the peritoneum, which then sloughed, and at last gave way. Such a slough of the peritoneum might not unfrequently be seen in the form of a thin opaque white membrane adhering to a part of the margin of the aperture. He added that he had seen two cases of cicatrices of chronic ulcers in the stomach, similar to those mentioned by Mr. Hawkins.

The President alluded to the case of M. Beclard as one of the same kind, and said that he hoped Mr. Curling would present the society with some account of his cases of ulceration of the duodenum in connection with burns.

The next meeting of the Society will be on the 12th of April.

## CASES OF HERNIA,

TREATED AT THE ST. MARYLEBONE INFIRMARY: WITH CLINICAL REMARKS.

By B. PHILLIPS, Esq. F.R.S.

THERE is no subject connected with the practice of surgery which has been more carefully studied than hernia; but the variety which these diseases present is so great, that the matter is far from being exhausted.

I wish to call attention to two cases of hernia lately under treatment, which presented peculiarities worthy of serious attention.

A woman, aged 62, was admitted to the infirmary with a tumor in the right crural region. She had great abdominal tenderness, and some nausea. She stated that this tumor had existed for some years; that she had supported it with a truss, and that it had never occasioned her much inconvenience. Her bowels had been irregular in their action for some time; and they had not been relieved at all since the previous Monday, a period of four days. When the tumor was examined, it was rather tense, irregular, and tender; the abdomen was tumid, and painful on pressure; the pulse was quick; the tongue was dryish and coated; and there was occasional vomiting of a suspicious character. When I saw her she had had two purgative and one turpentine clyster; but they brought away with them no fecal matter. Under these circumstances—the tumor being large, and of long standing, and the symptoms not very pressing—I directed that cold applications should be made to the tumor, and that she should take at intervals of three hours the following dose:—

**Ex. Coloc. Comp. gr. iij. ; Ol. Carui, gtt. ss.**

After twelve hours the following enema to be administered :—

**Ol. Ricini. Ol. Tereb. aa. ʒvj. ; Liquor. Potassæ, ʒiss. Beef-tea, ʒviij.**

The bowels were not moved by the pills ; but the injection brought away with it a large quantity of fecal matter, which was followed during the next twelve hours by two more evacuations. The symptoms of strangulation gradually abated ; the tumor in the course of the succeeding day was much lessened. During the next 48 hours there was increase of peritoneal tenderness, some fever, and no evacuation. Similar means to those previously used were again had recourse to, and with success ; but these troubles recurred again and again during the following ten days, but ultimately gave way, and the patient was discharged cured.

Mary Brown, aged 60, was admitted into the St. Marylebone Infirmary on Monday, Dec. the 6th. She complained of nausea, pain over the abdomen, and a tumor in the right groin. She was immediately seen by the resident physician, who ordered a purgative enema, cold lotion to the tumor, and turpentine fomentation to the abdominal surface.

At three o'clock I saw the patient, and found her with a moist clean tongue, a quiet pulse, some little nausea, and no great abdominal tenderness, though there was some tympanitis. The purgative enema had returned, but it brought no fecal matter with it.

She stated that the tumor in the groin had existed for many months, but had occasioned her very little inconvenience ; that the tenderness was perceived on Saturday ; that it had continued to increase, though slowly, and that it was accompanied by slight nausea. She stated farther, that the bowels had not been relieved since Thursday. The symptoms being so little pressing, and no means besides the purgative enema having been used to procure an alvine evacuation, the following means were ordered to be used :—

**R Ext. Coloc. Comp. gr. iv. ; Ol. Carui, gtt. ss. 4tis horis.**

And if the bowels were not affected by six o'clock on the succeeding morning, the following enema to be used :—

**Ol. Ricini, Ol. Tereb. aa. ʒiv. ; Liquor. Potassæ, ʒj. Beef-tea, ʒxj.**

On the succeeding morning, between three and four o'clock, after having taken four pills, she had an extremely copious offensive stool, of very unequal consistency. Spite of this the enema was administered at six, and was retained.

At one o'clock on the 7th she was again seen by me. The nausea had somewhat

increased, the tongue was less moist, and the pulse, though a little more frequent, had somewhat lessened in power. The abdomen did not appear more tense or more tender on pressure, and the size of tumor was lessened. She was ordered to have beef-tea in small quantities, and two drachms of brandy every two hours, under the careful supervision of the resident physician, and to continue the turpentine fomentations. I also directed that if any of her symptoms became more urgent I might be sent for.

She appeared comfortable when seen at seven o'clock, and continued so until nine, when she felt more sickness, and some stercoraceous vomiting occurred, accompanied by great depression. The resident physician ordered her to have ether mixture every two hours, and to have a mustard plaster to the abdomen. At twelve o'clock P.M. I was sent for : I found her still sick and very low. I ordered her some warm brandy and water, and determined to ascertain whether, in spite of the copious stool, a portion of intestine might be found in the sac. Upon cutting through the integuments and superficial fascia, a tumor was found very like a tumid congested gland : there was not the slightest vestige of sac around it ; neither was there any intestine under it. This knuckle of omentum, for so it was, was firmly adherent to the adjacent tissues over its whole extent. Under those circumstances the ring was enlarged, and the parts brought together. She never rallied, and died in the course of the morning.

She was examined thirty-six hours after death. The abdomen was still tympanitic ; the intestines inflated with gaseous fluid ; and there was a certain quantity of diffuse peritonitis, affecting mainly the surface of the large intestines. The inguinal region was carefully examined, and a portion of the omentum was found in the condition already described. By the side of this omentum there was no channel sufficiently large to allow of the descent of the intestine ; but just at the neck of the sac there was a cul-de-sac about half an inch long, in which a portion of the cylinder of the ileum was found concealed, and to which it adhered so closely, that when it was gently pulled it gave way at a very small point, and fecal matter escaped. Although at this point there was no sensible contraction at the diameter of the intestine, and although the inflammatory action did not extend beyond a third of its circumference, there was an appearance which might lead to a belief that some obstacle to the passage of the fecal matter had long existed there. For about an inch from the point, the intestine formed a pouch as large as the finger of an ordinary glove, and full an inch long.

Whether such an affection of a small por-

tion of the diameter of the intestine be enough to prevent the peristaltic action at the point, and thus to cause an accumulation of fecal matter, is a point of much interest, but not easily determined. The existence of the diverticulum would lead to the belief that the obstacle, such as it was, had long existed, and that the action of the intestine had been directed to force a new passage.

In Mr. Henry Gibson's case, the patient, a boy of fourteen, had vomiting, pain, and hiccup; great tension, but no stools. He rejected purgatives as soon as he took them. The clysters came away without fecal matter. A suppository made of a small candle rolled in soft soap and salts was introduced, and in a quarter of an hour there was a copious discharge of feces, without abating the vomiting, hiccup, or pain. The parents objected to operation, and the boy died.

The abdomen was opened. The small intestines were found scarcely discernibly inflamed, and the large ones not at all. We discovered an "appendicula," dependent from the ileon, of the size and form of the little finger of an adult's glove: this was about two inches or more from the small portion of the intestine concerned in the strangulation, which small part was nothing more than a shallow sinus or cavity of intestine, as if forming another appendicle, and was the only part of the intestine involved in the hernial sac.

In Mr. Else's case the whole circumference of gut was not included. In Mr. B. Cooper's case there was a similar state of things.

The second case I have related possesses several points of interest. In the first place, it shows, like its predecessor, the inutility, to say the least of it, of using drastic purgative injections. It seems to me, by exciting additional irritation, if they arrive at the strangulated point, they are well calculated to increase the evil, and that in a large number of cases they totally fail in producing an evacuation. I have seen great evils to follow their administration in cases of malignant or other contractions of the gut. Frequent emollient injections are much more likely to break down hardened matter than a single drastic purgative one; and supposing the obstacle to be a malignant contraction, irritating substances cannot fail to increase the mischief. There are of course cases where irritants may be necessary in old or paralytic subjects. The injection I ordered in the preceding cases I have found very effective, and I believe it excites very little irritation.

This case also shows that the symptoms of strangulation in old people do not present the urgent character which they assume in younger people. If, therefore, constipation does not yield within a moderate space of time to ordinary means, it becomes necessary to operate for the relief of the gut, even though the symptoms of peritonitis be not urgent,

nor the feverish reaction considerable; because peritoneal mischief may go on insidiously, and, without manifesting much intensity, may destroy life. Still, where the hernia is old and irreducible, the ring is enlarged, and the chances of strangulation are not so great as when it is recent.

Another point of importance in the latter case is, that although a copious evacuation of the bowels occurred in a few hours after admission, and that without injection, it produced only a very slight remission of the symptoms at that time, and did not at all avert the progress towards a fatal termination.

Why the disease terminated fatally the post-mortem examination did not explain: the peritonitis was slight: it was not accompanied by any effusion; and it was very limited in extent. The gut was perfectly pervious: it did not seem that more than a third of its calibre had been in any way involved in the protrusion; and that point, not larger than a shilling, was only softened and adherent; and there was no apparent obstacle to the passage of fecal matter.

It must be borne in mind, that after symptoms of strangulation are fully developed, a clyster may bring away a large stool without giving decided relief, as in the case before us, because the part protruded may be a portion of the ileum, and the injection may induce the large intestines to expel their contents. Recollect, then, that what is so much to be desired, a copious evacuation, must not throw us off our guard; unless it produces a decided remission of the symptoms, it will usually be without any good result upon the disease. But in this case the evacuation was obtained not by enemata, but by medicines introduced into the stomach, and passing through the whole length of the digestive tube. Here we had a right to expect benefit from the occurrence: and we can only account for her death by assuming that the shock given to her constitution before her admission was too great for an old woman in broken health to rally from.

In many of these cases the injury done to the intestine is so great, that, even though it be liberated early, some chronic inflammation is set up in it, and the patient ultimately dies. I presume that in the first case some such mischief had been sustained, because of the difficulty which was experienced in getting the bowels to act after the symptoms of strangulation had disappeared. Some months ago there was a case here in which the presumption in favour of this condition of the intestine was still stronger; for there was copious vomiting of fecal matter for nearly two days after the intestine was liberated by operation, yet the patient did well.

There is still one circumstance to which attention should be made—the exhibition of *Ex. Coloc. C.*, et *Ol. Carui*. It may be

called an irritating purge. All that can be said with respect to it is, that I have not found it so; but I have only used it in cases of old subjects. Two or three years ago I had a patient with strangulated femoral hernia. The symptoms were not very pressing. Castor oil was administered without effect by the mouth and rectum, but it produced no evacuation. Small doses of sulphate of magnesia were administered every hour. Stercoraceous vomiting came on, but the bowels were not relieved. I determined to operate; the patient refused to consent to it then, and said she would risk it till the next morning. I then ordered her Ex. Coloc. C. gr. iv., Ol. Carui, gtt. ss. 3tiis horis, which was regularly given her; and when I saw her the next morning the intestine had returned, and she had had a stool.

### INCOME TAX.

*To the Editor of the Medical Gazette.*

SIR,

I HOPE you will be able to find room for these few lines in your next GAZETTE, that they may meet the eye of some individual who may have the inclination and ability to be of service to the country practitioner.

The income tax of Sir Robert Peel has struck my brethren and myself with much alarm; for the natural inference has occurred forcibly to our minds, that if we have been scarcely able to keep the wolf from the door when we paid twelve pounds a year for taxes, how shall we do it when we have to pay twenty-four. We live as frugally as possible in-doors; but, unfortunately, we have an expense without which we cannot lessen—I mean the purchase and keep of a horse, which, to a surgeon attending a Union, I assure you frequently costs more than he gets for his contract. The farmer is allowed to keep a horse free of duty to go to market; surely the surgeon should be allowed the same privilege to visit the suffering poor. Perhaps this may be thought too trifling a lessening of his expenses; but I am sorry to say that, little as it would be, it would in many cases be highly valued. The expense of horse-flesh to a country surgeon is very great; it is not merely the purchase and keep of the animal, but the additional expense arising from casualties to which the horse is liable. If his own horse is lame or sick, he must hire another to visit the patients of the Union, and pay twice as much for the day as he receives for his trouble.

I am no politician, and know little of finance but what is taught me every Monday morning by my butcher and baker, and the close calculations of the Board of Commissioners; but I think Sir Robert Peel would have earned more laurels as a minister, if he had applied his scale to the in-

some tax as he has done to the corn duty; but, according to his present plan, it acts most unequally: the wealthy man may curtail his luxuries, the easy man his comforts, but the poor man must be deprived of his necessities.—I am, sir,

Your obedient servant,

A COUNTRY SURGEON.

### SPONTANEOUS GENERATION.

OUR readers may remember the excitement caused in the year 1837, by the announcement that Mr. Crosse, of Broomfield, had observed the development of certain insects incident to the long-continued action of voltaic pairs. Little additional information on this mysterious subject has since transpired until Tuesday, the 15th instant, when a paper from Mr. Weekes, of Sandwich, was read before the London Electrical Society, detailing the successful repetition of Mr. Crosse's experiments. Among the cavilling which arose in connexion with the original experiments, the possibility was urged that the ovæ of the insects might be in the air. Mr. Weekes's experiments were so conducted, that this objection can be scarcely tenable. A well-charred block of beech, containing a circular groove to receive a bell-glass, was the base of the instrument. The groove was filled with mercury. A tumbler, containing the solution of silicate of potass, was beneath the bell. The silica was obtained by subjecting to a furnace heat a piece of fine black flint obtained out of the centre of a "boulder," selected from amongst those lying on the shore at Sandwich. The silica was united to the potass by a furnace heat; the result quenched in boiling water. The solution was immediately covered, and filtered under cover. All things being prepared, the voltaic current was sent through the solution on the 3d of December, 1841; and from that date to the present time the apparatus has not been disturbed. At the end of October, 1841, the first insect was observed. On the 16th of November five were discovered. Since that date insects have been repeatedly seen. We must not omit to mention that the bell-glass was placed in total darkness, the screen being only removed when the progress was being examined. Mr. Weekes mentioned that he has another apparatus in action, very similar to this, with the exception that the bell was filled with oxygen, and expressed an anticipation that he should sooner or later detect insect life there. This expectation was realized a few days ago. In an appendix to his communication, bearing date February 27, 1842, he states that on the previous morning he "perceived eight or ten full grown acari in vigorous locomotion on the inner surface of the air-bell."—*Times*.

## DRUGS ON SALE IN THE ENGLISH MARKET,

With their Prices and several Duties.

(From the Official Returns, March 15, 1842.)

AYLESBURY UNION.

To the Editor of the Medical Gazette.

SIR,  
PERMIT me to notice an error in the leading article of your last number.

In alluding to the Aylesbury Union, you mention Assistant-Commissioner *Wade* as having suggested that one medical man could undertake the duty of the whole Union.

Now Colonel *Wade* has, I believe, had nothing to do with the Aylesbury Union: he has certainly been distinguished for a more judicious and humane administration of medical relief than most of his colleagues; and, in the pamphlet of the Provincial Association, from which you have quoted, it is expressly stated that Mr. Assistant-Commissioner *Gilbert* formed the Aylesbury Union.

Trusting to your love of truth to correct the mistake which you have inadvertently made—I am, sir,

Your obedient servant,  
THE SECRETARY TO THE POOR-LAW COMMITTEE OF THE PROVINCIAL ASSOCIATION.  
March 29, 1842.

SOCIETY FOR RELIEF OF  
WIDOWS AND ORPHANS OF  
MEDICAL MEN,  
In London and its vicinity. (Etab. 1788).

A HALF-YEARLY general court of the members of this Society was held on Wednesday at the Gray's Inn Coffee House. Sir Charles M. Clarke, Bart. vice-president, in the chair.

It appeared from the auditor's report that the sum of £682 had been granted for the past half year to thirty-one widows and fourteen children of deceased members; and that £100 had been funded.

Certain resolutions of former courts, regulating the amount of subscriptions by the age of members, were finally confirmed; and other resolutions for the registration of the Society, agreeably to the provisions of the Acts of Parliament for regulating Friendly Societies, were, after some discussion, carried unanimously.

By this proceeding the Society will obtain the privilege of arbitration in case of dispute, and of investing its funds, upwards of £42,000 stock, with the Commissioners for the Reduction of the National Debt.

We beg to call attention to the advertisement of the Annual Dinner of this Society to take place on Saturday, the 9th of April. His Royal Highness the Duke of Cambridge in the chair.

FRENCH ANTI-SLAVERY JOURNAL.

We beg to acknowledge the receipt of a number of a French journal entitled *Annales*

*de l'Institut d'Afrique*. It is dated Jan. 1842, and is the first number for this year. It contains, under the head of *Passeé et Avenir*, a review of what has been done for the abolition of slavery during the past year; and this is followed by articles on the characters and virtues of negroes, on Toussaint l'Ouverture, a report of the discussion on the slave-trade in the Chamber of Deputies on the 24th of January, &c. &c.

We heartily wish success to a journal and an institution whose object is the removal of the foulest stain upon civilization.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED  
CERTIFICATES.

Thursday, March 24, 1842.

W. V. Beadle, Bristol.—H. Wright, March, Cambridgeshire.—W. R. Shlell, Newcastle-upon-Tyne.—R. Roper, Sheffield.—H. B. Square, Kingsbridge, Devon.

LECTURES  
ON THE  
PRINCIPLES AND PRACTICE OF  
PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

*Enteritis: its symptoms; causes; treatment. Mechanical occlusion of the intestinal tube. Colic. Colica pictorum: its symptoms, complications, treatment, and prevention.*

SOME of the diseased states of the intestinal canal, while they differ a good deal in their essential nature, have yet many characters in common. Colic; ileus; enteritis; mechanical obstruction of the tube. It will be convenient, therefore, to consider these disorders in succession, and, in some degree, in connexion with each other.

In *colic* we have pain of the abdomen; pain of a twisting or wringing kind, occupying generally the umbilical region; vomiting; and costive bowels. Similar pains are apt to occur in diarrhoea; but they are transitory, and are then termed *gripings*, or more learnedly  *tormina*. When they are violent, and more permanent, and, above all, when attended with constipation, they constitute colic.

You have not forgotten the symptoms of *peritonitis*. They are, briefly, pain in the abdomen, increased on pressure; and fever.

Now if, to the symptoms of colic, you add the symptoms of *peritonitis*, you have the symptoms of *enteritis*: by which word I desire to express the disease that is commonly called *inflammation of the bowels*. The term has lately been extended so as to signify any and every form of inflammation which any portion or tissue of the intestinal canal within the belly may suffer; but I use it in the old-fashioned meaning. Cullen

makes two species of enteritis. One of these consists in inflammation of the mucous membrane of the intestinal tube: he calls it enteritis *erythematica*. That is not the disorder I am about to speak of; but the other of his species, the enteritis *phlegmonodes*. I say that in colic, we have abdominal pain, constipation, and vomiting. In peritonitis, the functions of the stomach and intestines are not, necessarily, affected: in enteritis they are. There is inflammation, not merely of the peritoneal coat, but of the cellular tissue uniting the several tunics, probably of the muscular tissue also, and often of the whole substance of the bowel at the inflamed part.

When the intestinal channel is any how closed up, and a bar placed to the passage of its contents, the symptoms of colic are very apt to ensue; and at length, the obstacle continuing, fatal inflammation is set up.

The term *ileus* is applied, I believe, to those cases, whether inflammatory or not, in which, by an inverted action of the intestines, their contents are carried, in a retrograde course, into the stomach, and thence out of the body by vomiting.

Having made these explanations, I shall now address myself more especially to the consideration of enteritis.

It is of much practical importance to discriminate between enteritis and the disorders that resemble it; and particularly to distinguish it from colic. When it commences, as it sometimes does, by distinct rigors, and is attended by thirst, a hot skin, and a hard and frequent pulse, there is no room for doubt. But it often begins insidiously, with mere colicky symptoms; the pain, at first, is not much augmented, it may even be somewhat eased, by steady pressure. If we mistake colic for enteritis, the error is of no great moment; but the opposite mistake, which is more common, may be fatal. Blood-letting, and the other remedies of enteritis, will not aggravate the mere colic; they may even, though unnecessary, relieve

the patient. Some of the remedies of mere colic are, however, highly dangerous when there is inflammation of the bowels. Physicians may fall into this error: patients who choose to prescribe for themselves, commonly do so. They take stimulants, cordials, carminatives—the pleasantest and nearest at hand is a glass of brandy, or of gin. And in true colic these means are frequently of great service: but they exasperate the symptoms, and increase the mischief when the disease is enteritis. Indeed treatment of this kind will sometimes urge colic into enteritis. If the case be ambiguous, you must act upon the most unfavourable supposition, and treat the complaint as if you were sure that inflammation was present.

The pain of enteritis is increased by pressure. The pain of colic is not only not made worse, but it is actually mitigated often, by pressure; and it usually intermits entirely. I know that when there is simply flatulent distension of the intestines, pressure does sometimes increase the patient's uneasiness; but the uneasy sensation is very different from that acute sensibility which belongs to inflammation of their peritoneal covering. In enteritis there are also *paroxysms* of severe pain, determined, probably, by the peristaltic movements, or by the temporary distension, of the inflamed parts of the bowel; and the pain has frequently a twisting character: but there is not any thorough intermission. There is a duller abiding pain between the sharper fits. It is to be observed also, as a diagnostic circumstance, that, as in peritonitis, the patient lies on his back, with his knees drawn up, and is fixed in that position, and for the very same reasons. If, in his agony, he tosses about his arms, the trunk is kept motionless, and the respiration is thoracic: whereas in mere colic the mode of breathing is not altered, and the patient is apt to be turning and writhing in all postures, and out of one posture into another.

The nausea and vomiting are often most distressing. The patient not only rejects immediately whatever food, drink, or medicine he swallows, but he has fits of retching, when the stomach is empty. In some instances, matters are cast up having the appearance, and something of the odour, of liquid *fæces*: or resembling, at any rate, the offensive fluids which are found in the small intestines after death in these cases. I cannot say that I have ever seen genuine excrement ejected, unequivocal ordure: yet this may well happen if it be true that clysters, introduced into the rectum, have been voided through the mouth. Such a phenomenon would show that the whole tube was

pervious; that there was no mechanical obstruction.

Although the fever, in the outset, may be high, and the pulse strong and hard, it soon becomes (as in all acute abdominal inflammations) small and wiry; or weak, and like a thread. In bad cases, as the disease proceeds, the abdomen begins to swell, becomes tympanitic; hiccup sometimes comes on; the pulse intermits or beats irregularly; the extremities grow cold; the features are sharpened and ghastly; cold sweats break out; the pain ceases perhaps; and the sphincters relax. The head is generally unaffected. Now and then delirium occurs late in the disease; but much more frequently the intellect remains clear to the very last. Death begins at the heart, and takes place in the way of asthenia.

You may probably have observed that the symptoms which I have been describing are just the symptoms which the surgeon so frequently encounters in cases of strangulated hernia. The symptoms of that surgical complaint are, in truth, most commonly at least, the symptoms of enteritis, caused by the forcible closure of the bowel. Obstruction to the passage of the contents of the gut gives rise to its inflammation. And we often find, after death preceded by the signs of enteritis, an internal mechanical obstruction—an internal strangulated hernia. In some cases, bands or strings of coagulable lymph, the products of bygone inflammation, have formed snares (so to speak) for the gut, which at length they catch and constrict. They do no harm till some coil of intestine gets beneath or beyond them; and then they strangle it, as the phrase is. I have twice seen (as I think I formerly stated) the appendix vermiformis prove the immediate cause of fatal internal hernia. In one of these cases, the person had been a private patient of Dr. Macmichael; and I went with him to examine the body. The free end of the appendix had become adherent to the mesocolon; and so a loop was made, through which a portion of the gut had passed. In the other instance, which I saw in Edinburgh, the appendix was literally tied round a piece of the intestine. Sometimes, again, there is intussusception: the upper part of the tube slips into the lower, fills it up, obstructs it; and inflammation fixes it there. Or it may be that a chronic thickening of the coats of the intestine has narrowed its channel; or a tumor presses upon the intestine from without; or some foreign substance, or morbid accumulation, plugs it up within; in all which cases a chronic disorder passes at length into acute inflammation. A very small hernia at one of the usual orifices—not large enough to manifest itself externally—is sometimes the

cause of the obstruction ; even though only a portion of one side of the gut may be nipped in the aperture.

Sometimes, but according to my experience less frequently, there is no mechanical impediment to account for the constipation. In all cases, whether there be mechanical obstruction or not, the inflamed portion of the gut is of a red or dark colour ; distended by its gaseous or liquid contents ; covered often, on its peritoneal surface, with coagulable lymph ; or adherent to the contiguous organs. When the gut is mechanically closed, the part which lies on this side the obstacle, as we follow the natural course of the channel, is inflamed ; the part which lies beyond it is pale, contracted, and, to all appearance, healthy. The line of demarcation is abrupt and strong ; and it is determined by the obstacle. And the distinction between the healthy and inflamed portions is usually as sudden and decided, when there is no apparent obstacle. I mean that up to a certain spot the intestine is red like a cherry, or dark like a grape, large, and smeared (perhaps) with lymph or with pus ; while immediately beyond that point, and throughout the remainder of its course, it is white, empty, and shrunk up into the semblance of a cord. The pathology of these last forms of the disease is full of difficulty. Some have held that the contracted part was the original seat of disease, namely, of *spasm* ; and that the upper adjoining portion of intestine became distended and inflamed in consequence of such spasm. Without attempting to explain these phenomena, which are comparatively unfrequent, I content myself with observing that it is the distended part which is the really inflamed part, and that its muscular coat appears to have lost its natural contractile power—not (I fancy) from overstretching, as now and then happens to the urinary bladder—but from the effect of the inflammation.

The inflamed portion of bowel is often of a very dark colour, and even almost black, from the great congestion of blood in its tissues. Now this black colour has sometimes been erroneously set down as an evidence of gangrene. You must not trust to the mere colour, however. If the coats of the bowel be firm, and if the peculiar odour of gangrene be wanting, you are not to conclude that mortification has taken place, simply from the dark appearance of the intestine.

Enteritis, not dependent upon any mechanical occlusion of the bowel, may arise under the operation of the ordinary causes of internal inflammation : cold and wet, for instance, applied externally, and especially to the feet and legs. Cold is thought to be particularly injurious in this way when the exposure happens soon after a meal : pro-

bably because at that time the digestive organs, being in activity, receive a more copious supply of blood.

The mechanical impediments that occur *within* the bowel, are still more various in kind than those which constrict it from *without*. Hardened faecal matters : intestinal concretions. Some of these are curious, and I shall hereafter have a word or two to say respecting their composition. Persons who are in the habit of taking a good deal of magnesia, or of chalk, to relieve acidity and heartburn, are liable to have these substances accumulate, and become indurated in the intestines. They generally begin to collect, I believe, around some accidental nucleus : and such a nucleus may very readily be supplied. A cherry-stone, a fish-bone, a gall-stone, that has found its way into the bowel. Even a pill, prescribed to cure, may thus come to kill one's patient. Dr. Prout was asked to analyse certain odd-shaped, triangular bodies which had been voided at stool, and were supposed to be gall-stones : but he found that they were specimens of Plummer's pill, which had defied the solvent action of the gastric juice, and had passed into, and lingered in, the bowels. Unbruised mustard-seed, and carbonate of iron, are other remedial substances which, injudiciously administered, have collected in hard masses, and produced intestinal disease. It is seldom that we can discover, during life, what is the exact nature of the mechanical obstacle : but I have observed this peculiarity in most of the cases in which I have known it produced by *intussusception*, that after severe and sudden symptoms of obstruction and inflammation, *blood* has been passed by stool. Sometimes the included portion of bowel itself sloughs away, and is expelled *per anum*.

Inflammation of the bowels requires very much the same kind of treatment as peritonitis : indeed, the disease is in most cases peritonitis, and something more. The patient must strictly abstain from every sort of stimulus, and confine himself as much as possible to the horizontal position. He must lose blood also from the arm, and the earlier the better. The lancet is not to be withheld merely because the pulse is small. If the artery becomes fuller, and its beating more distinct, under venesection—nay, if the patient does not become faint—the first bleeding should be a large one. This is not only the safer plan, but in the long run it is the most economical of the blood and strength of the patient. As in simple peritonitis, the abdomen must be covered with leeches, and afterwards with fomentation cloths. Should one spot or region be more painful and tender than another, on that part the leeches are to be accumulated. It may be requisite to repeat

the venæsection and the leeching once, or twice, or many times; the propriety of such repetition depending upon the urgency and obstinacy of the symptoms, and upon the age and state of the patient. I am speaking of idiopathic enteritis, and of its earlier stages. In the advanced periods, when feebleness of the pulse is associated with tympany of the belly and coldness of the surface, it betokens weakness and sinking, and the tendency to death by asthenia; and, consequently, it then indicates support rather than depletion. So also when the enteritis is not idiopathic, but consecutive—when we have reason to believe that it arises out of a firm mechanical impediment—our employment of blood-letting must needs be modified by that circumstance.

One point in the management of enteritis, requiring great caution and judgment, relates to the exhibition of purgative medicines. The costive state of the bowels is apt to be looked upon as the main evil, and their evacuation as the chief indication of treatment; but great mischief, I apprehend, is likely to arise from the exclusive pursuit of that indication. I am still speaking of the idiopathic disease, where it is presumable that no mechanical impossibility exists to the passage of the feces. Purgatives given by the mouth are often rejected by the stomach, with great distress to the patient. If they are retained, and fail to operate, they must do more harm than good. Certainly they should not precede the venæsection. I well remember, though it is now many years ago, being myself badly treated for enteritis. Being ill, in a strange place, I sent for the nearest practitioner, who happened to be a very ignorant man. Finding that I was sick, and that my bowels did not act, he gave me, for two or three days in succession, strong drastic purges, with no other effect than that of increasing my sickness, and adding to the abdominal pain I suffered. I was then seen by a most intelligent physician (this was before I had paid any attention to physic myself), and the first thing he did was to have me copiously bled; and the immediate effect of that bleeding was to send me to the night chair. And I am persuaded that when evacuations follow the administration of purgatives in such cases, they are often owing to the blood-letting and other anti-phlogistic measures that are employed at the same time. These are the opinions of Dr. Abercromby also, who says, "I confess my own impression distinctly to be, that the use of purgatives makes no part of the treatment of the early stages of enteritis; on the contrary, that they are rather likely to be hurtful until the inflammation has been subdued." It is an instructive fact, that when purgative medicines *do* operate during the height of the inflammation, the stools they

produce are merely watery; and it is only after the inflammation has been reduced that *feces* are discharged, and then in such quantity sometimes as to show that they must have been shut up in the bowels during the period of active inflammation.

You should wait, then, for the effect of other measures, blood-letting, leeching, fomentation, before you give active purgatives by the mouth; and in all stages of the disease, whatever laxatives are given should be of the mildest kind, such as are least likely to excite irritation of either the stomach or bowels.

The same objections do not apply to enemata, which sooth while they evacuate the lower parts of the canal. You will read or hear of great service done by an infusion of tobacco, or by the smoke of tobacco, thrown into the bowels through the rectum. Dr. Abercromby speaks of a weak infusion of the leaves as being a remedy of very general utility. It should, I apprehend, be a *weak* infusion to be at all safe; but, of my own knowledge, I can tell you little or nothing about it. I do know, however, that the injection of a large quantity of merely warm water is often of much use: from two to six pints, for example, thrown up gradually and gently. Indurated feces are softened and brought away in this manner, and the warm water acts as an internal fomentation.

Of internal medicines I believe the best you can give is a combination of calomel and opium, in such proportions as will restrain the purgative qualities of the calomel. The opium allays pain, and, perhaps, relaxes spasm; the mercury tends to arrest the inflammatory action; and the more immediate effects of this combination are often found to be, a settling of the irritable stomach, a disposition to diaphoresis, and an improved pulse.

To sum up then, bleeding, and calomel and opium, are to be resorted to for checking the inflammation; and when that is in great measure abated (and probably not before) it will be right to give some mild laxative to clear out the bowels. There can be none more suitable or convenient than castor oil. But before we venture upon purgatives by the mouth it will be proper to wash out the bowels by lavements of tepid water. These injections *may* sometimes have mechanically a beneficial effect upon the parts concerned in the inflammation; untwisting, for example, a twisted bowel; or setting free the half incarcerated intestine.

There is one very important point in the treatment of enteritis that I have yet to mention. I have told you that in the advanced stage of the disease symptoms of sinking often come on; a total cessation of pain, failure of the vital powers, and coldness of the body. These symptoms, this collapse and approach

to syncope, are generally considered to denote gangrene, and, therefore, a hopeless state of disease. Yet in many cases which have proved fatal after similar symptoms, not a trace of gangrene has been discoverable. So that this unpromising change in the symptoms does not always indicate a morbid condition which is necessarily mortal. And if the patients are to be saved at all, they are to be saved by wine and support. We must combat the obvious tendency to death by asthenia.

"A man, aged forty, was affected with enteritis in the usual form, for which he was treated in the most judicious manner by a respectable practitioner. On the fifth day the pain ceased; the pulse was 140, and extremely feeble and irregular; his face was pale, the features were collapsed, and his whole body was covered with cold perspiration; his bowels had been moved. In this condition (says Dr. Abercromby, from whom I quote the case) I saw him for the first time. Wine was then given him, at first in large quantities, and, upon the whole, to the extent of from two to three bottles during the next twenty-four hours. On the following day his appearance was improved; his pulse 120, and regular; the wine was continued in diminished quantity. On the third day his pulse was 112, and of good strength, and in a few days more he was well."

Dr. Abercromby relates other cases to the same effect; and most physicians, I suppose, have occasionally seen such. They teach us that we must not abandon our patients in despair, even under the most adverse circumstances. If diarrhoea should supervene with this state of collapse, opiates must be joined with the wine. External warmth is also a powerful auxiliary.

I know of no cases of disease more painful to witness or to treat than those which result from invincible obstruction of the intestinal tube. They are attended, at length, with enteritis; but they differ much in some respects from what I have called idiopathic enteritis. The inflammation is an accident or consequence of the obstruction; or of the means used to overcome it. They happen usually somewhat in this manner. A person thinks it expedient to take some aperient medicine. It has no effect. He repeats the dose. It causes pain and gripings, and probably sickness also; but still the bowels are not moved. Enemata are employed. They bring away, perhaps, some hardened feces; but there is no farther relief. Meanwhile the patient may have a clean tongue, a quiet pulse, a cool and soft skin, and a supple and painless abdomen. Purgatives of a more drastic kind are tried, but tried in vain; and the physician is summoned.

Now the first thing which you have to do,

when called to a case of "obstruction of the bowels," is to search narrowly whether there be not some unsuspected external hernia. All delicacy must be waived; and every part of the body, where hernia may possibly shew itself, must be submitted to inspection. If none be found, the rectum, and in women the vagina, must be severally explored. Stricture, or a quarry of impacted feces, may possibly be detected in the one: a uterine or other tumor, pressing upon the bowel, may perchance be felt through the other. I shall never forget the shock I once experienced on being sent for to see a woman, of middle age, who was *in articulo mortis*, and who, as I was told, had for some days been labouring under sickness, pain in the abdomen, and constipation. In her left groin there was a large palpable strangulated hernia, which had not been detected by the practitioner in attendance, simply because it had not been looked for; and which was discovered only when it was too late.

Remember, therefore, that in every case of obstinate costiveness, with signs of inflammation within the abdomen, it is absolutely necessary, for your own credit and subsequent comfort, as well as for your patient's safety, to make diligent and thorough enquiry after such herniae as may be recognised externally.

But often you find nothing of the sort, and then you are at liberty to prosecute with more energy and decision the purgative plan of treatment. You prescribe strong doses of jalap and calomel: black draughts. The stomach being irritable, you give *pills* of cathartic extract, and repeat them at short intervals; or large doses of calomel, ten grains or a scruple, three or four times in succession. You inject stimulating clysters. Then you are driven to croton oil: and at last, in some vague hope of relaxing spasms, to opiates. If symptoms of inflammation spring up, you put fairly in force the remedies of inflammation; and especially blood-letting. But all is in vain. The medicines are vomited; or, if retained, they serve but to augment the patient's distress, producing or renewing the pain and the nausea. It is extraordinary how comfortable the patient sometimes becomes upon the intermission of these active attempts. Now and then he suffers tormina, or has fits of retching; but in the intervening periods his sensations and outward condition may be those of perfect health; only there is no alvine discharge.

Now, under these afflicting circumstances, the question will force itself upon you—how long am I to pursue the purgative system? Common sense, and common humanity, answer—you must stop it the instant you are convinced that there is a mechanical obstacle, which cannot be overcome. To persist in the use of drastic purgatives after

that conviction, is to inflict wanton and needless torture upon the patient. But how are you to know this? That is one difficulty. And how are you, believing that it is so, to satisfy the patient's friends that his disorder is irremediable; and to resist their importunity to try this and that; and to persuade them to look passively on, while their relative is slowly perhaps, but surely, perishing? These are great and terrible difficulties.

You will be urged by all imaginable suggestions; even the most absurd. Crude mercury may perhaps be one. Pounds of this metal have been swallowed in such cases; in the hope, I suppose, that it would force a passage by its weight. But the obstacle may be in an ascending coil of intestine. And if not, experience does not teach us to put any faith in this rude mechanical remedy. It has often done mischief, and seldom or never done any good. This metal is apt to become oxydized in the body, and then to produce very distressing salivation. This is an evil which I have known to occur, and to trouble the patient greatly, sometime after the ineffectual exhibition of large doses of calomel.

Dashing cold water over the abdomen and the lower extremities, is another rough expedient, which is sometimes successful in producing evacuations. It was adopted, after various other measures had failed, in the case in which the bowel was tied down by the adherent appendix vermiformis; and it caused the emptying of that part of the canal which lay beyond or below the internal hernia. It is plain that this partial success can be of little or no use; certainly of none that can compensate for the shock and annoyance of the cold affusion.

Let me not, however, be misunderstood. I do not say that you are to abandon all hope when purgatives (and, if need be, blood-letting) have failed, after a few trials, to obtain evacuations from the bowels. Nor even that you are necessarily, for that reason, to give up the use of purgatives. The intestines may be torpid and insensible to ordinary stimuli, and really require strong rousing. Dr. Abercromby mentions the case of a gentleman whose bowels were locked up by an accumulation, as the result showed, of black hardened feces. The obstruction, which had resisted the most active purgatives, and was accompanied by an evident and painful distension of a part of the abdomen, yielded at once to the repeated application of galvanism to that part: each application being immediately followed by a copious evacuation. Here the flagging muscular action was restored, apparently, by the galvanic stimulus. Very lately I attended an elderly lady, who, from Wednesday morning to the next Monday noon, had had no alvine relief, notwithstanding the employment of

the most active cathartics. She suffered frequent paroxysms of pain and vomiting: but the abdomen was scarcely, if at all, distended; nor was it tender. At length she complained that what she vomited was stercoraceous—to use her own words, “what came upwards ought to have passed the other way.” It was a thin, brown-coloured, ill-smelling fluid. Dr. Mayo and Mr. Arnott were now associated with me in this case, and they touched and felt the abdomen as I had previously done. The lady observed that their hands were heavy; and she fancied that the pressure they made had displaced something within. And I believe that it was so: for before our consultation in the next room was over, word was brought us that the bowels had acted. She had passed a liquid motion precisely resembling the stuff she had last vomited. The next day, with one of several similar stools, a hard lump was voided, which proved to be a gall-stone, as big as a small walnut.

As large quantities of warm water had without difficulty been injected, I infer that the concretion had been impacted high up in the bowel, probably at the valve of the cæcum. Some years previously the lady had suffered severe abdominal pains, which at the time were ascribed to the passage of a biliary calculus through the gall-ducts.

In this instance there was no evidence of any strong contractile efforts of the bowel above the place of obstruction.

Large enemata—as much as the intestines will patiently receive—gradually and gently introduced, and repeated three or four times a day, may sometimes succeed in breaking down and washing away masses of hardened excrement: and if these enemata are composed of milk or beef-tea, and are suffered to remain as long as they will, they may answer another important purpose; they may contribute sensibly to the nourishment of a patient who cannot retain food in his stomach. They are generally very soothing and comfortable; allaying tormina, and abating sickness: and they are adapted to every stage and variety of the complaint.

There are, however, cases in which we arrive at the melancholy but sure conviction that some mechanical impediment has rendered the bowel absolutely and hopelessly impassable. We fear this when, the constipation being obstinate, we discover a tumor, or hardness, in some part of the belly: or when we receive a history of some former inflammatory attack, since which the bowels have been habitually difficult to regulate. Our fears are strengthened when the patient feels that the injections reach a certain spot, and there always stop; and that the intestines rumble, and roll, and propel their contents downwards to the same spot, and no farther. And this is the distinctive

symptom upon which I desire to fix your attention. The abdomen gradually enlarges, especially if the patient is able to retain food; the intestines fill up above the obstacle; and then throes of pain occur, *spasms* the sufferers usually call them, attended with sickness; and during these pangs you may feel, and if the abdomen be uncovered, you may see, immense coils of intestine, as big perhaps as one's arm, rise and roll over, like some huge snake, with loud roarings and flatulence. When this takes place the time for giving purgatives is certainly over. The distended bowel requires no stimulus; it acts, and strives with all its power, but strives in vain, to overcome the opposing barrier. If you would consult your patient's ease, if you would not embitter and abbreviate his slender remnant of life, harass him no farther with active remedies. In some cases violent inflammation quickly supervenes, and death arrives in a few days: in others, the patient survives, without any evacuation from his bowels, but with long intervals of ease and comfort, for four, or five, or six weeks. Even a brief respite may be of infinite value; giving time for the arrival of distant friends—for the settlement of worldly concerns—and for preparation of the spirit against the inevitable hour.

It is to these circumstances of irremediable disease that *opiates* are eminently adapted. Even when the symptoms are less desperate, they are not without their use. I cannot better express what I think upon this point than in the words of the first Heberden, who says: "The probability of advantage from anodynes has determined me to recommend them; and experience has strongly confirmed this judgment. Under the protection of an opiate I have successfully given more and stronger purges than would have staid without its help. The patient's strength has been kept up by some refreshing sleeps: and even in hopeless cases, in which the dying person is harassed by unspeakable inquietude, he may be lulled into some composure; and without dying at all sooner, may be enabled to die more easily. Lord Verulam blames physicians for not making the euthanasia a part of their studies: and surely, though the recovery of the patient be the grand aim of their profession, yet where that cannot be obtained, they should try to disarm death of some of its terror; and if they cannot make him quit his prey, and the life must be lost, they may still prevail to have it taken away in the most merciful manner."

I have spoken of these cases as being irremediable: but perhaps I have spoken somewhat too absolutely. Life may, sometimes, be saved by a surgical operation. The gut may be punctured above the seat of obstruc-

tion, and suffered to discharge its contents through what is called an *artificial anus*. This expedient is feasible, however, in those cases *only* in which the obstacle is situated near the termination of the large intestine; i. e. in the rectum, or in the lower part of the descending colon; for here only can we ascertain, with any thing like certainty, the exact place of the impediment, and here only may the colon be pierced, from behind, without injury to the peritoneum. Under no other circumstances, in my opinion, would an attempt to relieve the patient, by cutting down upon and opening the bowel, be justifiable. An artificial outlet in the loin would probably be less disgusting to the patient, and less offensive to others, than if it were in front of the body. I am not aware that the operation has ever been done in this country. It has been practised, successfully, in France. The mode of performing it I am not competent to teach you. In an appropriate case I should think it right to *mention*, though I should be slow to *recommend*, this *anceps remedium*. The risk of failure, and the penalty of success, should both be set fairly before the patient. The choice between certain death, on the one hand, and the chance of living with a very loathsome bodily infirmity, on the other, must be made by himself\*.

It remains that I should say something more respecting *colic*: which may exist independently of enteritis, and of mechanical occlusion of the bowel; although the three are very often combined and intermixed in the course of the same disease.

In colic there is pain in the abdomen, constipation of the bowels, vomiting often: and these are symptoms which occur also in enteritis. The pain is a twisting or wringing pain generally, round the navel: and such is the character of the exacerbations of pain experienced when the bowels are inflamed. These are the points of *resemblance* between the two maladies: and it is of much importance, as I told you before, to observe their *differences*; and to note the marks by which the one may be distinguished from the other. It is, then, an essential difference that enteritis is attended with fever, and with tenderness of the belly. The pain is increased by all kinds and every degree of pressure; and the patient, fixed in the supine position, breathes with the intercostal muscles only, and carefully avoids any movement which would call the abdominal muscles into action, and so compress the inflamed bowel. In colic, on the other hand, the circulation is tranquil; there is no fever; and the pain is even mitigated by pressure. The patient

---

\* See an interesting paper on this subject, by Mr. Erichsen, in the *MED. GAZETTE*, April, 1841.

will lie on his belly for ease; nay, he will press it, with the whole weight of his body, across the back of a chair, and obtain comfort by that manœuvre. During the paroxysms the pain is often most violent; what the old writers call *dolor atrox*—atrocious pain: but there are intervals of complete ease. Even when the pain is worst, the patient tosses and shifts from one posture to another in search of relief; and he does not wear that anxious and apprehensive aspect which we see in those who are labouring under enteritis. The pain arises, I imagine, from the distension of the bowel, here and there, by gas; or, it may be, from spasm; or from both these states at once. At any rate, it is often associated with audible flatulence, and with evident outward spasm. The abdomen is hard, and drawn spasmodically inwards towards the vertebral column; and its muscles are partially and strongly contracted, gathered up into lumps and knots. None of these circumstances belong to enteritis.

However, there is good reason for believing that, even in mere colic, the pain may sometimes be augmented by pressure. When a portion of the gut has become rapidly distended, considerable uneasiness may result from its forcible compression; although, as Dr. Abercromby states, the kind of pain can generally, by attention, be distinguished from the sensitive tenderness of an inflamed peritoneum. Luckily, if such pain on pressure should lead us to mistake a case of pure colic for a case of enteritis, the error is on the safe side: and we must always bear in mind the tendency remarked in colic, when the complaint is neglected, or badly treated, to run into actual inflammation. In fact, as any obstacle to the passage of the alimentary matters through the bowels may give rise to colic, colic is sometimes merely the first step towards acute inflammation arising out of a continuance of the obstruction. And having told you that colic may be thus produced, I have at once introduced you to a large class of its causes which have already been spoken of in the present lecture as frequent causes of inflammation also.

But colic, like inflammation of the bowels, sometimes arises without any apparent or detectible obstruction, of a mechanical kind, to the free transit of the contents of the alimentary tube. And there is one particular form of colic, that requires a separate notice. The *colica Pictonum*—so called from its great frequency, heretofore, among the Pictones, or inhabitants of Poictou—is produced by the slow introduction of the poison of lead into the system.

Now the colic which has this origin is not to be distinguished, in its ordinary symptoms, from any other kind of colic. But the abdominal pain is usually, in such cases, a

part only of more general disease. It has received, in different places, a variety of names. *Colica pictonum*; the painter's colic; the Devonshire colic; the bellain of Derbyshire; the dry belly-ache of the West Indies. In all cases it acknowledges the same cause—the gradual entrance of lead into the body.

In this country we see the disease more often in painters than in any other persons. They use, as you know, white lead in the preparation of their colours; and they are perfectly familiar with this terrible colic. We see it also in all workmen whose occupations bring them habitually into contact with preparations of lead. No doubt there are very great differences in the susceptibility of this effect of the poison of lead. Persons have been known to suffer *colica pictonum*, in consequence of their sleeping for a night or two in a recently painted room. On the other hand, I have myself seen a patient who became affected with the disease, for the first time, after working with white lead for 19 years. Generally the first attacks of colic are well recovered from. The obstinate constipation of the bowels is at length overcome: the patient obtains ease; and forthwith recurs to his previous habits: and after a period, which varies in different individuals, he is again laid up with the colic. Even the primary attacks are usually attended with pains in the head, and in the limbs; sometimes with cramps; sometimes even with epilepsy and coma. At length, in one of these attacks of colic, or after one of them, when the violence of the pain, and the costiveness, have yielded to treatment, the patient finds that he has lost the full power of using one or both of his hands. The wrists, as the patients express it, *drop*. You see at once what is the matter, by the characteristic state of the arms and hands. The extensor muscles of the hands and fingers are palsied: so that when the arms are stretched out, the hands hang dangling down by their own weight; and the patient is unable, by any effort of his will, to raise them. The palsy is local: it does not proceed from any diseased condition of the nervous centres. The affected muscles waste; and the atrophy is very remarkably seen in the bundle of muscles composing the ball of the thumb. Even from this condition the patients often are capable of complete recovery. But if they persist in following their former calling—or if, without knowing it, they continue to be habitually exposed to the exciting cause of the disease—they become miserable cripples, fall into a state of general cachexia, and sink at length under some visceral disease. The poison accumulates in the body, and saps the powers of life. Francis Citois, a native of Poictou, who published an excellent and one of the earliest accounts of the disease,

in the year 1617, has drawn the following graphic picture of its effects. Its cause was not at that time suspected. Speaking of the wretched sufferers, he says, "Per vicos, veluti larvæ, aut arte progredientes statuz, pallidi, squallidi, macilenti conspiciuntur; manibus incurvis, et suo pondere pendulis, nec nisi arte ad os et cæteras supernas partes sublatis, et pedibus non suis sed crurum musculis, ad ridiculum ni miserandum incassum compositis, voce clangosâ et streperâ."

The course of the disease is usually such as I have just described it. The colic happens first, perhaps several times: and then arrives the palsy. But in a few instances I have known this order reversed. The wrists have dropped, when there had been no preceding colic.

The great cause of this fearful malady was first made out by our distinguished countryman, Sir George Baker. He set on foot an enquiry into the origin of what was called the *Devonshire colic*; so common was it in that county. He found, first, that it occurred chiefly in persons who drank the *cyder* manufactured there: and, by degrees, he traced the source of the malady to the admixture of lead with the *cyder*; either designedly, for the purpose of sweetening it; or by the inadvertent employment of lead in the construction of the *cyder* mills and vats. It was under circumstances of the same kind that the colic of Poictou originated. Preparations of lead were used—not fraudulently, but openly and honestly—to prevent the wines of the country from turning sour; the injurious influence of lead upon the human body not having then been ascertained. So also, equally convincing proofs of the adulteration of *rum* by means of lead, giving rise to frequent attacks of dry belly-ache in the West Indies, are given by Dr. John Hunter, in the *Medical Transactions*. I invite your attention to his papers, and to Sir George Baker's, on this subject. They afford a capital specimen of medical research and reasoning. Various causes, as you may suppose, had been assigned for this disorder. These are one by one investigated, and set aside; until, by this method of exclusion, the real source of all the mischief is detected. Sir George Baker's papers contain a great deal of curious and useful information in respect to the various modes in which this poison of lead may find its way, without being suspected, into the animal economy. The subject is one of vast importance in its relation to medical police; but my limits will not allow me to follow it beyond the point where it ceases to be directly connected with the practice of physic.

*Colica pictonum* is seldom fatal as colic; or during the persistence of the abdominal symptoms: yet enough instances of death occurring while the colic was present, but

from other accidental causes, have now been collected, to enable us to say, that no appearances have been met with in the intestinal canal, calculated to explain the pain or the constipation. Andral relates five cases, in which the body was carefully examined after death preceded by the painter's colic. He found neither inflammation, nor any remaining trace of spasm. The intestines were neither dilated nor contracted, but of their natural texture and appearance. Merat, who has written a good treatise on this form of colic, gives the dissections in four fatal cases: fatal, as I mentioned that they sometimes are, by the supervention of coma. There was no discoverable mark of disease; the alimentary canal was empty, and the large bowels contracted; as they were also found to be in rabbits which had died of lead colic. For animals are susceptible of the disease, and it may be produced in them by the slow impregnation of their bodies with the specific poison. Dogs, cats, and rats, that inhabit houses and manufactories wherein lead is much used or prepared, are known to be attacked both with colic and with palsy. With respect to the contraction of the large intestine in these cases, we must not be too ready to attribute it to spasm; for the bowel, when empty, is apt to be contracted.

When the palsy has been of any continuance, the affected muscles not only shrink and waste, but undergo a structural change, which is obvious to the sight. They become pale, almost white, dry. John Hunter examined the muscles of the hand and arm of a house-painter, who died, while thus paralytic, in St. George's Hospital. He found them of a cream colour and opaque; instead of being of a purplish red, and semi-transparent. And, since his time, lead has been detected in the palsied muscles, and in the brain, by chemical analysis. It is doubtless conveyed, by the blood, to all parts of the body: why it fastens solely or chiefly on particular muscles, or particular nerves, nobody knows. The pain it occasions, whether in the abdomen or in the limbs, is generally thought to be neuralgic. It is one of the poisons that do not appear to find a ready exit from the body. Very recently, a most curious symptom, pathognomonic, I believe, of the presence of lead in the system, has been pointed out by Dr. Burton: and now that it has been pointed out, one can hardly understand how it escaped discovery so long. It is a blue or purplish line running along the edges of the gums, just where they meet the teeth. Dr. Burton first noticed this six years ago, but wisely refrained from making his observations public until he had had time and opportunity enough to satisfy his mind that he was not mistaken. A paper of his on the sub-

ject was read at the Medical and Chirurgical Society last January (1840). I cannot resist the temptation to read to you the notes of a case which has subsequently occurred to me in the hospital. Mary Anne Davis, a middle-aged woman, presented herself with dropped wrists. It was an exquisite example of palsy of the extensor muscles of the hands and fingers. She could raise her arms, but her hands hung down like the talons of a bird, or like the fore paws of an erect kangaroo. This began nine weeks before. She complained of pain, beginning under the nails, stretching up the back of her hands, and reaching sometimes to the elbows. The bottoms of her feet had also been tender; and at night were burning hot.

Seeing the dropped wrists, we thought immediately of the poison of lead. But the patient was a female. We do not often see these effects of that poison in women; for obvious reasons. At first we could get no clue to the mode in which lead could have found its way into her system. Her husband was a broker. She had not been living in a newly-painted house: and had (she said) no concern with lead in any way. Lead often creeps in, however, through undetected channels, and I could not help suspecting it here. Mr. Pyper, my clinical assistant, soon elicited another part of her history, which added to our suspicions; namely, that before the palsy occurred, she had had pains in the abdomen, and costive bowels, for five days together. Nay, she had a recurrence of colic after her admission. This was a strongly corroborating fact; but what clinched the proof was the discovery of a decided blue rim along the edges of nearly all her gums. This conclusive evidence led to further cross-examination; and at last it came out that some of her sons (she had seven) occupied their leisure time in the preceding summer with making bird-cages, and painting them green, in the one room in which she habitually lived. The case altogether was a very neat one.

Mr. Tomes pointed out to me some interesting circumstances which led him, at one time, to think it probable that the colour is produced by some chemical action between the tartar that forms on the teeth, where they meet the gums, and the lead which pervades the system. This woman's teeth, like those of many in her rank of life, were loaded with tartar. In one place was visible a stump, level with the gum, and surrounded by a ring of tartar; and *there* was also a corresponding border of blue. In other places there were gaps, where teeth once were; here there was, of course, no tartar; and here there was no blue line on the edge of the gum. I do not know exactly in what manner the chemical union arises, but the colour depends, I believe, upon a *sul-*

*phuret* of lead, formed somehow by the action of sulphuretted hydrogen upon the metal.

This discovery of Dr. Burton's is not a mere piece of curiosity, but is likely to be of use in various ways. In the first place, it may settle the nature and cause of many doubtful cases; as it did, indeed, of the one just narrated. The poison of lead causes pains which resemble, and no doubt are sometimes mistaken for, the pains of rheumatism; it has other obscure consequences too: and an inspection of the gums may often greatly elucidate such cases. Dr. Burton finds that small quantities of lead given as a medicine will produce the phenomenon. In two instances it occurred within two days. One of these patients had taken 15 grains of the acetate of lead in that time; the other 24 grains. A correspondent of his produced the blue rim in 24 hours; viz. by four doses, of 5 grains each, exhibited every 6 hours. He finds too that the lime remains distinct after death; even more so than during life. It may afford valuable information therefore to the medical jurist in cases of suspected poisoning with the salts of lead. It is, I say, an *early* consequence of the absorption of lead. It will teach us, as the mercurial affection of the gums teaches us, that the medicine is pervading the system; and admonish us to look out for, and guard against, colic. It may apprise workers in lead that their caution has been insufficient; that the poison has entered; and that they are in peril of belly-aches and palsy. It is a capital diagnostic sign also between colic so arising, and colic from other causes; and between colica pictonum, and the pain of inflammation of the bowels.

In the *treatment* of colic—and especially of the lead colic—the great indication is to get the bowels to act. If the pain of the belly be increased on pressure, if the pulse be at all accelerated, if the face be flushed, and there be the slightest approach to fever, it will be right to take blood from the arm. It is a measure of safety as regards the possible existence of inflammation: and if there be no inflammation present or impending, it will tend to remove the spasmodic state of the muscles which goes along with, and perhaps chiefly constitutes, the disease. External warmth should also be applied; diligent friction, with some stimulating liniment; or, what is much better, a mustard poultice, or a turpentine stupe. My colleague, Dr. Wilson, has been very successful in relieving these patients, by putting them into a hot bath, and having a large quantity of the water in which they are immersed, thrown gradually into their bowels by means of a proper syringe. The bath presently becomes polluted, to the great satisfaction and refreshment of the patient. It will generally be

expedient to give a full dose of calomel and opium; ten grains of the one with two of the other. Sometimes the effect of the opiate is to suffer the bowels to empty themselves; showing that the previous difficulty was probably spasmodic. Usually the calomel and opium will soothe the vomiting, the restlessness, and the pain; and then a full dose of neutral salts, or of castor oil; or (if these do not succeed) of the last-named remedy, castor-oil, quickened by one or two drops of the oil of croton, will give rise to free evacuations from the bowels; and the patient soon returns to his ordinary state of health. It is sometimes necessary to repeat this practice, this alternation of purgatives and anodynes: but when once the bowels have been freely moved, the disease, in general, becomes very tractable.

At La Charité, in Paris, there is what is called a specific mode of treatment followed. It is complicated and rough, but not a whit more successful than the simpler plan which is universally adopted in this country. You may see it described, if you are curious on the subject, in most of the French books. I think it is given in detail in Ratier's *Formulary of Hospital Practice*.

Some have recommended salivation for the cure of the painter's colic, on the principle, I conjecture, of driving out one metallic poison by another. But the two may combine, for aught I know, to plague the patient. The practice is quite unnecessary.

You will be consulted about the palsy which arises from lead, and especially to remedy the dropped wrists, which render the patient incapable of earning his livelihood. Now in the early stages of the palsy, and in its primary attacks, you may often succeed in effecting a cure. Electricity has been thought useful, applied in the way of sparks at first, and of slight shocks afterwards, along the muscular parts of the extensors of the fingers. It accelerates the recovery to give the hand and fingers the mechanical support of a splint, made for that express purpose, and so contrived that the hand and fingers are kept extended through the greater part of the day. Patients labouring under this kind of palsy resort to the Bath waters for a cure: and I learn from a gentleman who once held the office of house-surgeon to the hospital there, that the physicians have much more faith in the use of the baths, with shampooing, and in splints and blisters to the palsied muscles, than in electricity. The warm douche is a promising expedient: the electro-magnetic apparatus, perhaps, still more so.

According to Andral and others, who have had more experience of that drug than I have, there is no form of palsy so likely to be benefited by *strychnine* as this which proceeds from the poison of lead. I should

recommend you to try the safer methods of binding the hand to a splint, and stimulating the muscles by friction, shampooing, or electricity, before you resort to that active poison.

It is observable of this disease, as of many, and, indeed, of most others, except certain contagious febrile diseases, that when once it has occurred, it is much more liable to occur again, upon a repetition of the exciting cause, than before. It is of very great moment, therefore, that they who are necessarily exposed to the poison of lead—as painters, plumbers, printers (who handle leaden types), colour-grinders, potters, and glass-blowers (who use the oxide of lead in their respective manufactories), shot-makers, workers in lead mines, and so on—it is of great importance that these persons should be made aware of the means which are best adapted for their protection against the injurious agency of the poison: and we ought to be able to give them advice in that matter. The rules for their guidance are short and simple; and if carefully observed, I believe they will generally prove successful. They resolve themselves into cautions against the admission of the metal or its compounds into the body through any channel.

1. To prevent its introduction through the skin minute attention to *cleanliness* is necessary. The face and hands should be washed, the mouth rinsed, and the hair combed, several times in the day; and bathing and ablution of the whole body should be frequently performed: also, the working clothes should not be made of woollen, but of strong compact linen; and they should be washed once or twice a week at least; and they should be worn as little as possible out of the workshop: and some light impervious cap might protect the head while the person is at work.

2. Care should be taken that none of the poison be admitted into the system *with the food*. The workmen, therefore, should not take their meals in the work-room, and should be scrupulous in cleansing their hands and lips before eating.

3. The entrance of the poison into the air-passages during respiration should be guarded against as much as possible. Masks have been recommended for this purpose: none, probably, would be more convenient or more effectual, than Mr. Jeffreys' orinatal respirator.

There is a notion prevalent in some places, which apparently has some foundation, that the free use of fat, and of oily substances, as food is a preservative against the colic. A physician near Breda informed Sir George Baker that the village in which he lived contained a great number of potters, among whom he did not witness a single case of lead colic in the course of fifteen years; and he attributed their immunity to their having

lived very much on butter and bacon, and other fat kinds of food. De Haen also was told by a physician, the proprietor of a lead mine in Styria, that the labourers there were once very subject to colic and palsy; but that after they were exhorted by a quack doctor to eat a good deal of fat, especially at breakfast, they were exempt from these disorders for three years. This a kind of prophylaxis that is very easily adopted.

More recently Liebig has asserted that "the disease called painter's colic is unknown in all manufactories of white lead in which the workmen are accustomed to take as a preservative, *sulphuric acid lemonade*, a solution of sugar rendered acid by sulphuric acid."

If this be so, the lemonade must protect the system by converting any other salt of lead, which might find entrance, into an *insoluble* sulphate: solubility being necessary to give efficacy to any poisonous substance.

ON

## CONCUSSION OF THE BRAIN\*.

By R. A. STAFFORD,

Surgeon Extraordinary to His Royal Highness the Duke of Cambridge; Senior Surgeon to the St. Marylebone Infirmary.

DURING the last year there have been several injuries of the head in this Infirmary. I have had under my own care no less than four or five cases of concussion of the brain, and two of fracture of the skull. No injuries are more important than those of the head; and as they are of common occurrence, and constantly happening in private practice, more especially in the country, I shall make a few observations upon their symptoms and upon their treatment.

My object will be, in the present lecture more especially, to speak of concussion of the brain. Concussion of the brain is caused from violence—either from falling from a height—a blow with a stick or bludgeon—or from something falling upon the head; for instance, a man may be working upon a scaffold, his foot slips and he falls upon his head; or he may be thrown from his horse; or in defending himself he may receive a blow upon the head; or again, a tile or a brick may fall from the top of a house and strike him. These are the usual ways in which such injuries are received. When any one of them have happened, the patient falls apparently lifeless to the ground; he is quite insensible, and when taken up he has no power whatever over his limbs; he is at first considered as killed, being pale and cold, looking like a corpse. It is observed, how-

ever, that he breathes. He is taken to the first surgeon's house, or laid upon a shutter and carried to an hospital. When arrived at either of these places, more symptoms of life appear: he is still cold and senseless; his breathing is more perceptible, but he vomits. The reason of vomiting is the immediate connexion of the brain and the stomach by the sympathetic nerve; the brain being shocked or injured, the stomach sympathizes, the action of that nerve being impaired. The surgeon examines his head, and finds he has received a blow upon it; that there may or may not be an extensive wound; but there is no fracture. He examines the eye, and finds the iris stationary, and rather contracted than dilated. He finds also that the patient rather improves in sensibility than otherwise; consequently he considers that he has concussion of the brain. Now comes a most important practical point. A crowd collects round the door, and the first question which is asked is "Has he been bled?" The answer is, no! "What? not bled!" is the cry. "Surely he ought to have been bled!" One of the most intelligent of the crowd then steps forward and enquires of the surgeon how the man is, and asks "but do you not think, sir, he ought to be bled?" The surgeon, being intelligent, makes this answer, "Sir, the fact is, this poor man has concussion of the brain, and is at present in a state which we term collapse, that is, his powers of life are so diminished, that if I were to bleed him he would die. When reaction returns I then shall bleed him, and perhaps largely, according as his symptoms may require." I recollect, when I was house surgeon to St. Bartholomew's Hospital, which is now some years ago, I was attending for Mr. Abernethy a neighbouring institution. It happened to be a very windy, gusty morning, and tiles, chimney-pots, and bricks, were tumbling about in all directions. One of the boys of the establishment went out for a holiday, and had the misfortune to have a sign board blown upon his head. He fell to the ground senseless, and was carried home in this state. I was sent for, and found him pale, cold, and almost lifeless; his pulse was hardly perceptible, his breathing heavy, and he was constantly vomiting. His extremities were cold and motionless, and the pupil of the eye contracted. I found he had concussion of the brain, and was in a state of collapse. An apothecary of the old school was standing by his bed side, just beginning to tie up his arm to bleed him. When he saw me he gave up the case to my care, as I was attending for Mr. Abernethy, to whom I was responsible. I declined bleeding the boy, and the old gentleman was much surprised. We argued the matter, he saying

\* Being the substance of a lecture delivered at the St. Marylebone Infirmary, Nov. 10, 1841.

it was the usual practice. I would not give up the point, telling him respectfully, that when reaction returned, I would do it, but I was sorry I could not in the stage of collapse; giving him my reasons. He appeared displeased that I should be so obstinate, and differ with one of his age and experience: however, I was firm; I bled the boy at the proper time, and the case did well.

The treatment in the stage of collapse in concussion of the brain is, to apply warmth and give stimulants. First put your patient's feet into hot water; then put him to bed, having had it warmed; apply hot bottles of water to his feet; pour down his throat, if his sickness will let you, a tea-spoonful of brandy and water every now and then, which is the best stimulant, and let him lie quiet. You must however be careful of your stimulant; as soon as warmth begins to return, and the pulse rises, it must be left off, or you will feed the inflammation which is to follow. Here I shall mention a case of extreme collapse. It happened that five people, while at work, were precipitated from a scaffold, at the height of four stories. Three of the five were killed on the spot; two survived, and were brought to St. Bartholomew's Hospital. One experienced a compound fracture of the leg, with other injuries; and the other, who came under my care, as house surgeon, had concussion of the brain, besides dislocating his ankle, breaking the other leg, fracturing two ribs, and being bruised all over; he was in almost a lifeless state—as cold, and I may say as pale, as marble; it could only be known that he breathed by putting a mirror to his mouth. I sat by his bed-side with a bottle of brandy in my hand, and poured tea-spoonful by tea-spoonful down his throat. In twelve hours he began to change; he breathed, warmth returned, his pulse could be felt, reaction had taken place; in fact he lived. This case made a deep impression on my mind. It pointed out to me that we ought never to give up a patient in the stage of collapse, and I hope it will do the same to all of you; that is to say, while there is life there is hope. This man ultimately recovered.

In concussion of the brain, as warmth returns, so will the symptoms change. You will find that the patient now will begin to have a consciousness; if you shake him, he will rouse as if from a heavy sleep, and having muttered something, will fall again into a drowsy stupor. The sickness will continue, but the skin will become hot, and the pulse will gradually rise until it beats with violence. Now will be the time to bleed, and it must be done largely, even to syncope. Now reaction has really taken place, and we must employ all our means to keep down inflammation. It will not only

be necessary to bleed from the arm, but blood also must be taken from the head. Should the pulse rise, the patient must be bled again, and venesection must be repeated as often as the symptoms require it. The head also must be shaved, and a cold lotion constantly applied upon it. The bowels must be freely opened, which will be best effected by giving a large dose of calomel, combined with jalap, and followed by a black dose, besides which it will be necessary to keep the bowels open by saline purgatives, and to keep down fever by antimonials and other febrifuges. During the progress of the case, you will find perhaps that the patient will complain of pain in the head, first in one spot and then in another, perhaps over the brows, on the temples, the top of the head, or the back part. You will feel the spot, and you will find it hotter than the rest of the head; an application of leeches is the best remedy, as often as such a symptom occurs. After this treatment the patient will perhaps be better, but still, although you have bled him largely, both generally and locally, yet he will have headache, pain in the head, and a low muttering delirium; he will answer you a question tolerably reasonably, but will immediately forget what he said, and go on wandering. You will rouse him again; he will again answer you rationally, but he will fall into the same low muttering. He will complain that he cannot bear the light, and it will be necessary to darken the room. This perhaps will be four, five, or six days or more after the accident. You have repeatedly bled him from the arm, bled him locally from the head, used a freezing lotion on the head constantly, purged him, given him febrifuges, blistered the back of the neck, and even perhaps administered a dose or two of opium. You feel his pulse; it is rather low than high; soft, compressible, and not so frequent as in fever—perhaps about 80 or 90; the bowels have acted; the head is not hot; in fact you see no particular symptom to demand any particular treatment. You feel in your own mind rather puzzled. I have done everything this case requires, but something still is wrong. He certainly is better, but far from well. I have bled him until I dare go no further; I have reduced him in every way, until I fear to do more. What can I do? Ask yourself this question. I know the injury he has received. Suppose he were to die at this moment. In what state should I find the brain on dissecting it? Why, the dura mater would be congested with blood, the arachnoid membrane inflamed, and with perhaps considerable deposit of lymph upon it; the pia mater the same; and on cutting into the substance of the brain, instead of its natural colour it would be

florid, of a reddish blush, and points of blood-vessels would be seen all throughout its structure. The brain being in this condition, I have only one remedy I can depend upon, and that is mercury. I am afraid of lowering any more. In fact, I must give mercury until I touch the mouth.

I will now relate a case or two which came under my care in this Infirmary, which will illustrate this treatment. In June last Thomas Somers was precipitated from the top of a coach, and fell upon his head; he was taken up senseless. He remained in this state for an hour or two, when his senses gradually returned; but he answered questions, when roused, in a very confused manner, being also drowsy. When reaction was fully established, he was bled largely, and in the evening he was cupped on the temples. His head was shaved, and a cold lotion constantly applied. He was purged and blistered; and the bleedings, both generally and locally, was repeated as often as symptoms required. On the sixth day, although he was better, yet he still had pain in the head, and could not bear the light. He could answer a question correctly, but afterwards fell into a low delirium, muttering to himself, and his mind wandering on all kinds of subjects. His pulse was rather weak than strong, compressible, soft, and beating about 90. He had but little fever. He could not bear losing any more blood, or being more lowered. Under these circumstances I thought it better to give him mercury, just sufficient to make the mouth sore. I ordered him three grains of calomel, and a quarter of a grain of opium every six hours. From this time he gradually got better, and his intellects became restored. In four or five days his mouth was sore. The calomel was diminished in quantity, and at length omitted altogether. In two months he was discharged quite well.

The second case occurred about a month afterwards, and was not so severe as the last. This man fell from a ladder and struck his head. He was stunned for a few minutes, and then was brought into this Infirmary. Reaction soon returned, and he was bled, cupped on the head, and treated much the same as in the last case. Five or six days elapsed, and though better, he did not improve. He was still delirious, and appeared at a stand still. He took calomel and opium every six hours. He immediately began to amend, and in six weeks went away quite well.

I now shall mention a third case, the last of the kind which was admitted under me, one of extreme interest, one so melancholy and distressing, although the individual recovered, that it is even painful to tell the tale. It happened only four months ago. A man had lived with his wife on

very good terms, having had a family by her, and each attached to one another, when, having been married five years, he suddenly became insane, from jealousy, and in his mad fury he took an extreme hatred to his wife. He determined to murder her. He took the first opportunity, when she was off her guard, to take hold of the poker, and beat her on the head. She fell senseless to the ground, and lay for dead. He had method enough in his madness to know that he was amenable to the law; in fact, that he should be hanged for the crime. He took a razor, and cut his throat from ear to ear. He died. The neighbours, having heard a disturbance, and finding that it suddenly ceased, began to think it extraordinary. All was silence, a deadly silence! They broke into the room, and beheld the sad spectacle. The woman lying apparently dead, and her husband with his throat cut. The poor woman was brought into this Infirmary. On examining her head, she had an extensive laceration on the right parietal bone, which was fractured at the part; but there was no depression, and only the outer table of the skull was broken. She had no symptoms of compression of the brain, as the iris was at first contracted and afterwards it acted. She was delirious for some days, and after being bled &c., she was ordered calomel and opium every six hours. She took this remedy for seven or eight days, going on with the other treatment, and at length she came to her senses. It is affecting to relate, but the first words she spoke were, "How is my husband? How are my children?" The nurse prudently said they were well, but an incautious friend told her all that had happened. The shock was so great that she immediately became delirious again, and remained so for several days. After some time, she gradually got better, and left the hospital as well as could be expected under such unhappy circumstances.

These three cases appear to me to illustrate the benefit of administering mercury so as to affect the mouth in the second stage of concussion of the brain. I shall now offer an explanation of the *modus operandi* of mercury in concussion of the brain.

I before told you that you would find the dura mater, on dissection, congested with blood; the arachnoid membrane inflamed, with lymph deposited upon it; and the brain congested. The action of calomel on the brain produces the same effect as it does in iritis. It causes the absorption of all the deposited lymph on the membranes, and relieves, by the same rule, the congestion of the substance of the brain. In iritis we see the lymph deposited upon the iris in globules, and we know unless it is absorbed that it will become organized, and thus destroy the sight. We give mercury immediately to

salivation; and as the calomel acts we can see the absorption of lymph on the iris going on. It is gradually taken away until all is gone. The same effect, no doubt, is produced on the brain and its membranes; the lymph and effused matter is absorbed, and the congested vessels are stimulated and restored to a healthy action.

There are other cases of concussion of the brain less severe than those I have just mentioned, but still of a very serious nature. A man is thrown from his horse, and falls upon his head. He is stunned for a minute or two, and then gets upon him again; feeling excessively confused. He goes home at once, or rides on, thinking he will gradually get better. In a few hours headache comes on, and he becomes flushed in the face, and feverish. His friends about him now send for his medical attendant, who finds him in the state I have mentioned, with a sharp full pulse. He is bled largely, takes a dose of calomel, succeeded by a brisk aperient; applies an evaporating lotion constantly on the head, and is ordered low diet. The aperient is followed by saline medicines with a febrifuge; and with the occasional application of leeches, he gets much better in a few days. He begins to live as usual, but he finds his headache and other symptoms return. He is obliged to be put on a strict regimen for a length of time as to food, exercise, &c.; and perhaps it is found necessary that he should take mercury so as to affect the mouth. By way of example, I will relate a case.

**CASE.**—A gentleman of rank, although a remarkably good horseman, was riding round the Park, and his horse, being frightened, suddenly started and threw him, and he fell upon his head. He was stunned for a minute or two, when he got on his horse again, feeling excessively confused, and rode home. He immediately saw his medical attendant, who advised him to remain quiet, to apply an evaporating lotion on the head, and take very low diet. As he was no worse in the morning, he was ordered a brisk aperient, and to go on in the same manner. This description of treatment he continued for a few days, and he got much better. Being in high life, keeping an excellent table, and having a keen appetite, he could not resist the temptation before him. He did not eat much, but too much for the state of his head. He became flushed in the face, heated, and feverish. His pulse was much accelerated, head hot, and he felt a great nervous excitement: in fact he was worse than he ever had been. A consultation was held on his case, and he was ordered to lose blood repeatedly, by cupping, or by the application of a considerable number of leeches on the head, to go on with the former treatment, keeping the bowels regular, and of all

things, to keep on a strict regimen of low diet. He did so; but although better, he still had very distressing feelings in the head. Mercury was prescribed for him so as to affect the mouth. However, he continued very unwell. Being in parliament, he found his parliamentary duties too much for him; indeed his medical attendants would not allow him to go there, advising him to leave town. He did so. He remained in a very ambiguous state of health for a very long time, requiring the greatest attention and care. He was restricted in diet, taking meat but seldom, and all his food in a diminished quantity, and was obliged to lead a very regular quiet life; for whenever he deviated in the least from the plan laid down, his headache and feverishness returned, and his digestion became bad; having, at the same time, restless and sleepless nights. He continued in this state for nearly a year. His health was carefully watched, and I believe he owes his life to the strict attention that was paid to him. He has never been quite the same man since.

The description of cases like the one I have just related, are those which lay the foundation of ill health, disease of the brain, and sometimes insanity. You ought not, therefore, although the injury may appear slight, to think lightly of it. Treat it as serious—for it really is so when we consider their consequences after having treated the active symptoms. Keep your patient on a strict regimen of diet, regulate the bowels and the secretions, and enjoin the greatest quietude for a considerable period after the accident.

## MUSCLES OF THE EYE.

*To the Editor of the Medical Gazette.*

SIR,

You did me the favour, in the number of your journal for December, 1836, to insert a paper of mine on the functions of the muscles of the eyeball, in which I attempted to arrange them into two sets, by considering some as acting by the stimulus of the will, and, therefore, as voluntary muscles, and others as acting sympathetically or independent of the will, and, therefore, to be considered as involuntary muscles. I also attempted an arrangement of the nerves by which these two different actions are governed, by dividing them also into voluntary and involuntary. My reasons for supposing such difference in their functions to exist I then fully stated, and need not now again enter upon.

I have been much gratified, in reading Dr. Carpenter's *Principles of Physiology*, just published, to find that he takes up the same view, in many respects, which I advanced in my paper more than five years ago (and here I beg to state that I am not arguing for priority of claim, nor for originality in theory, but merely wish to compare statements made in my paper with those now made in the work above referred to, and which I think support my views, and lead me to suppose that my theory was not altogether visionary). Part of my theory was, that the upper division of the third nerve was voluntary, while the lower was involuntary or sympathetic only. My words are—"It is upon this division of the third nerve into its two branches that I mean to explain the action of the remaining muscles, and wish to show that the inferior or ganglionic portion governs the involuntary or sympathetic movements of the eye-balls, while the superior or ganglionless portion governs the voluntary motions. In order to support this theory that I have advanced, we must see if these two sets of muscles are so employed," &c. &c. I then proceed to give my reasons for supposing such difference in the action of the muscles supplied by the third nerve, to exist. I also considered the functions of the other nerves, endeavouring to show that the sixth nerve was purely voluntary, and that the fourth was involuntary or sympathetic only. I sum up my views in these words:—"Thus it is seen that there are three voluntary muscles, namely, the levator palpebræ, superior rectus, and external rectus; and two voluntary nerves, namely, the superior division of the third nerve, and the sixth; while there are four involuntary muscles, none of which act, except in sympathy with the voluntary muscles, and are supplied by two nerves, namely the inferior division of the third nerve, and the fourth."

Dr. Carpenter enters very fully into the particular actions of the different muscles of the orbit, and also the functions of the various nerves distributed to them, which I need not here quote. The conclusion, however, to which he comes he sums up in the following words:—"It will be remembered that this nerve subdivides into two principal branches, of which one supplies

the levator palpebræ and superior rectus, whilst the other is distributed to the internal and inferior rectus, and to the inferior oblique. Now the former appears to be of a purely voluntary character." Again he says, "There is good reason to believe, therefore, that the actions of the inferior branch of the third nerve are in great part automatic, while those of the superior branch are purely voluntary." The only difference between these two passages is this; that the word *sympathetic* or *involuntary* is used by me with regard to the functions of the inferior branch of the third nerve, whilst Dr. Carpenter uses the word *automatic*. Dr. C. also mentions Valentin's theory, which I believe to be very similar in principle to the one now referred to. I, however, never heard of his theory until reading the above work, in which it is quoted. Hoping you can find room for these few remarks,

I have the honour to remain,

Your obedient servant,

EDWARD F. LONSDALE.

82, Guildford Street, Russell Square,  
March 24, 1842.

## SCARLATINA.

*To the Editor of the Medical Gazette.*

SIR,

THE prevalence of scarlet fever during the spring and autumn of the past year has afforded me numerous opportunities of witnessing that disease in all its forms, from the simple efflorescence of the skin, with or without inflamed fauces, to the most severe and fatal malignant sore-throat. But the epidemic of last year possessed characters which are not, I imagine, very common under the usual attacks of this complaint. Some cases passed regularly through their course, such as it is usually described; in some there was no eruption, in others no sore-throat; in some the usual premonitory symptoms ushered in the disease, in others it came on at once in all its severity, destroying life in the space of a few hours. The chief peculiarity, however, was the tendency in most cases to terminate in glandular swellings or supurations in the neck, throat, or ears. When these glandular swellings suppurated well, and were allowed to open

of themselves, the patients were almost sure to recover; but when they were opened early, nature seemed jealous of the interference, and unwilling to complete the salutary operations in which she had been engaged.

I will not, however, detain you by any lengthened observations upon the forms of a disease which most practitioners had as good an opportunity of noticing as myself: my principal object in addressing you is briefly to direct attention to a mode of treatment of one of the *sequelæ* of scarlet fever, which I have found invariably to succeed, and which I have not seen noticed by others. The complication or consequence of the disease, to which I refer, is dropsical effusion or anasarca, which is of frequent occurrence whenever scarlet fever is prevalent. This affection is generally considered to be of an inflammatory character; and blood-letting, and other antiphlogistic remedies, are recommended for its removal. The general success of such measures is also fully established by the concurrent testimony of various authors; but during the late epidemic I had occasion to treat the disease in patients who had been so much debilitated by the previous attacks of fever, that I had not the courage to produce any further reduction of the powers of the constitution.

From having observed its power of strengthening the constitution, with, at the same time, a tendency to prevent inflammation and to increase absorption, I was induced to make trial of iodine. I prescribed it in the form of solution recommended by Lugol, viz.

*R. Iodine ℥j. ; Iodid. Potass. ℥ij. ; Aquæ 3vij. M. ft. Solutio Iodin. concentr.*

Of this solution I ordered from 5 to 10 drops for children, and from 10 to 20 or 25 to adults, three times a day in water. In the first case in which it was used it rapidly effected a cure; in consequence of which I prescribed it in every succeeding case that presented itself, and with the same complete success.

If iodine have not hitherto been employed for the cure of anasarca swellings after scarlet fever, I believe I shall have the happiness to have introduced to the profession a safe and an effectual remedy for a troublesome and sometimes obstinate affection: if others have employed it, I have the grati-

fication to add my feeble testimony to the good effects of a mode of practice not so well known or recommended as it seems to me to deserve.—I am, sir,

Your obedient servant,

E. COPEMAN.

Coltishall, March 24, 1842.

## REMARKS ON CONCEPTION.

*To the Editor of the Medical Gazette.*

SIR,

As the subject of conception is still involved in obscurity, allow me, through the medium of your columns, to endeavour to explain this wonderful and inimitable process of nature.

It is not, however, without due deference to the many distinguished physiologists that have preceded me in this important path of inquiry that I enter upon so mysterious a subject; but as my views will be found to differ essentially from those of every author, I am anxious that they should be made public, in order that their truth or erroneousness may hereafter be determined.

I am, sir,

Your obedient servant,

C. BLACK.

Chesterfield, March 22, 1842.

It is generally admitted that in the procreation of the human species the female furnishes the future being in a rudimentary state, which requires the co-operation of the seminal fluid of the male to perfect its development: but the method by which this effect is produced, or the exact channel through which the semen influences the ovum, has not at present been demonstrated. Some physiologists have asserted that the seminal fluid is transmitted into the Fallopian tubes, in which it comes into direct contact with the ovum which escaped from the ovarium during coition, and whilst in this situation impregnates it; while others affirm that it remains in the uterus, from which its influence is propagated by sympathy. To neither of these opinions can I subscribe, as will appear from my assuming the following positions:—

1st. That the semen passes no farther than the uterus, and that impregnation may, but does not generally, take place until the ovum enters it.

2nd. That the seminal fluid is absorbed by the mucous membrane of the

uterus, in consequence of which the vascularity of the organ is increased, which causes its subsequent enlargement and the secretion of the decidua vera, by which the ovum is impregnated.

With respect to the former position, it may be argued that if, after killing an animal, we immediately inflate its uterus by means of a blow-pipe inserted into the vagina, no air is observed to pass into the Fallopian tubes, which effect is evidently owing to the position of the valves at the mouths of these tubes. If, then, air is inaccessible to them through the cavity of the uterus, how is it possible for the seminal fluid, which is far less subtle—nay, of an adhesive nature—to enter them? Gravitation can produce no effect in this instance, inasmuch as the Fallopian tubes are inserted into the angles connected with the superior border of the uterus; from which and the preceding data it may, I think, be inferred that the semen cannot pass mechanically beyond the cavity of the uterus. On this supposition I shall endeavour to show that impregnation of the ovum does not generally take place until it has passed into the uterus. Now it is well known that when a woman conceives, the uterus begins to enlarge, and to throw out upon its inner surface a quantity of coagulable lymph, which is subsequently organized, and then styled the decidua vera. These occurrences always take place previously to the introduction of the ovum into the uterus in cases of pregnancy. Unless these effects are produced no conception ensues, although the ovum shall have passed into the uterus. Hence it is absolutely necessary that, to induce pregnancy, a decidua be present. If this is not the case, the ovum, on arriving at the cavity of the uterus, either attaches itself to its mucous surface, becoming a hydatid or mole, or passes out with the next menstrual flux. As it is the nature of every organ, in its rudimentary state, to enlarge in proportion as it is endowed with a greater or less degree of vitality, it is only rational to suppose that the ovum would manifest this disposition to increase during its passage along the Fallopian tube, provided it were impregnated in the ovarium. This, however, is not manifest unless it is retained in the Fallopian tubes, in which situation it occasionally acquires a perfect

development; but even in this situation it is never developed without the presence of a decidua, which, being a production of the mucous membrane, cannot be formed in the ovarium; consequently, no conception can, in my opinion, take place in that organ. Although it is admitted by most authors that a woman may again conceive while there is yet a foetus in utero, I am inclined to believe that such is not the case, and that when superfœtation does exist, it takes place at the time of the original conception, and that, owing to accidental circumstances, the ovum is retained in the Fallopian tube, in which situation it may require a longer period for its full development.

In reference to my second position, there is sufficient ground to believe that the semen is absorbed by the mucous membrane of the uterus. The apparent functions of the mucous membranes are to secrete and to absorb. The secretion of mucus, of the menses, and of the succus intestinorum, are evidences of the former; whilst the effects produced upon the system by an opiate taken into the stomach, or injected into the rectum, are sufficient proofs of the latter. If, then, the mucous coat of the intestines is capable of absorbing, this property cannot reasonably be denied to that of the uterus, inasmuch as no essential difference exists in the anatomy of these structures. We may, I think, therefore, regard it as capable of absorbing the seminal fluid when the latter is presented to it, which function is, probably, heightened by the great excitement into which the genital organs are thrown during coition. To explain the effects of the semen after its absorption, it must be regarded as a specific cause acting upon a certain organ which is expressly designed for the reception of its impression, in producing which impression its action bears a seeming analogy to that of the vaccine lymph in the formation of pustule. It must, however, be remarked, that its operation does not tend to the formation of pus, but first to an increase in the vascularity of the uterus, and subsequently to a deposit of coagulable lymph on its mucous surface, and an evident growth of its muscular structure, which are the immediate effects of such vascular turgescence. In a few days the deposit of lymph becomes or-

ganized by the vessels of the uterus extending into it, thus converting it into a vital membrane, which, in my opinion, possesses all the generative virtues of the seminal fluid in its blood, for the purpose of impregnating the ovum immediately on its attachment to its surface. As soon as this attachment takes place, the vessels of the decidua in contact with the ovum extend into the latter, and by this means afford a direct channel for the decidual blood, imbued with all the properties of the semen, to produce its specific influence on the embryo of the future being.

ON THE  
APPLICATION OF PHYSIOLOGY TO  
THE STUDY OF THERAPEUTICS  
AND TOXICOLOGY.

By THOMAS WILLIAMS, M.B.

Lecturer on Forensic Medicine at the Webb  
Street School of Anatomy.

(For the Medical Gazette.)

*General considerations.* — In these days of thriving and advanced general knowledge, it can scarcely be imputed to the cultivators of medical science that they ill-perceive or imperfectly understand the intimacy with which its several departments are bound together. A general agreement in the belief is expressed, that it is a fabric of which the unity and completeness are inseparable from the equable progress and mutual dependence of its elements. There is notwithstanding a remarkable discrepancy in the prevalent feeling with reference to the proportions which, respectively, they should be allowed to assume, or the comparative value and importance which should be assigned to each in its place in the fabric. There are not wanting at present many who more willingly would celebrate the praises of a practical man than encourage the labours and reward the exertions of an original investigator. The truth of this observation extends undiminished to the fact, that the opinion entertained by professional men themselves respecting the value of any given branch of their science, will, by rapid diffusion, impart its character to, and even determine, the general opinion of society. The feeling which now pervades the public mind, that the competency of a practitioner for

the management of disease is to be estimated inversely as the measure of his acquaintance with general science and physiology, must undeniably be viewed as the overgrown remnant of that notion, which, in less illumined days, prompted men "*se ἐμπειρικούς ab experientia nominant.*" The dependence of the profession upon the public has entailed upon its members a reaction of this feeling to such severe and oppressive extent, that the desire of distinction, which is the happiest incentive to study in the student, is extinguished in its earliest rise, and the young practitioner is soon lessoned in the painful belief, that the course best calculated to guide to success in practice must consist, first, in imposing a servile silence upon his "love for science;" and then cultivate studiously the "complaisant" and the "suaviter in modo." As the first origin and present sway of such injurious and discouraging sentiments are referrible to the conduct of the profession itself, so it is certain that their removal can only be accomplished by the improving learning, extending acquirements, and augmenting superiority of its members. With men of the present generation, the happier view progressively spreads, that every impulse of advance which medicine can receive will have its source in the thrivings of some of its dependent sciences.

There are no two branches within its pale between which more direct dependence exists than physiology and therapeutics; for nothing can be more flagrant than the error of conceiving that the *ratio medendi* of an agent, without the assistance of physiology, can receive elucidation through the channel of common observation. In all instances two requisites are involved in the right settlement of the mode in which alike a mild remedy and a virulent poison affect the living system. It is essential first to understand the part which the element, organ, or system, upon which its operation is concentrated, fulfils in the sum of the organism. The consideration of the action of the remedy will then resolve itself into determining the extent and nature of the difference between its function under the influence of the agent, and its function in the natural and undisturbed state. While, however, this is indicated as the right path

through which to prosecute the study of these combined sciences, it is designed here neither to assume that the present standard of physiology renders practicable the attainment of such perfection, nor to understate the complex difficulties of the subject. But, for illustration, let it be supposed, that in consequence of the affinity of the bichloride of mercury for albumen, upon its direct introduction into the blood, by combination with its albumen—the properties of the latter are neutralized or modified, as those of an alkali under the agency of an acid—it follows that, unless the compound of the bichloride and albumen be isomorphous with the albumen itself, all the functions in which this principle is engaged will be morbidly affected. Two advantages attend this method of inquiry. If the transformations which albumen undergoes preparatory to its ultimate assimilation were correctly understood, the symptoms of the induced condition might be made the clue to ascertaining the function which albumen performs in the economy; and the inference may further be received, that the effects of agents, upon the system, are not in every instance referrible to a direct or abstract affinity between them and the organ on which their influence is manifested, but rather to the circumstance of their combination with a certain element of the blood more immediately engaged in the function of an organ. Albumen, under normal circumstances, does not appear to be involved in the agency of the kidneys; and it is coincidentally known that mercury seldom affects the secretion of urine. The peculiar animal principles of the salivary secretion, “osmazome,” and “salivary matter,” may, on the other hand, be regarded as albumen modified in the apparatus of the glands. In thus selecting albumen for the purposes of explanation, it will be admitted that, although it constitutes a proximate element, from its numerous uses and relations in the system, the question has been presented in its most complex form. It will be subsequently found that, in estimating the effects sustained by a *system* of organs under the operation of a given substance, the subject will assume a more definite and certain character. In a therapeutic sense it is important that the difference between inorganic and vegetable agents should

be recognized and understood. In the administration of a mineral substance no benefit can be anticipated from its *assimilation* with the structures of the body; for this combination can only occur in very minute proportion. A vegetable principle, however, in virtue of the number and chemical relation of its ultimate elements, possesses the power of ministering to the nutrition, and itself of constituting an integral portion of the body. It is not required to state that the animal derives its materials not from the mineral or inorganic, but from the vegetable kingdom: the intervention of the vegetable is required for the preparation of inorganic material for the purposes of a higher transformation. When, therefore, a mineral acid or metallic oxide is given, they enter into permanent union with the structures with which they are first brought into contact. These compounds are subsequently eliminated by the several secreting organs in an *unchanged* state. This is remarkably the case with the salts of mercury, arsenic, lead, bismuth, iron, and copper. In ultimate and correct fact, it cannot consequently be stated that the effects of these inorganic substances are due to the substance as originally administered, but rather to the compound, formed by its admixture with the elements of the blood. In accordance with this view, it has occurred to me that no less useful than important facts may be ultimately developed, by first combining the agent to be tried with *liquor sanguinis*, in order to the previous formation of the compound, which, in the ordinary method of administration, is produced *after* its introduction into the blood. The insolubility of the resulting product would probably require its injection into the vein. If the effects correspond with those of the unmixed agent, as ordinarily exhibited, the correctness of the conclusion can scarcely be denied that, under the two circumstances, although apparently dissimilar, the resultant effects would have for their cause the agency of the same combination. From this view it is obviously inferrible, that the albuminate of mercury, when *injected* into the blood, ought to affect the system in no way different from the chloride of the same metal when taken into the stomach. I may here state, that I have in view the determination

of this question by experiment; but the importance of attending to this alteration of chemical constitution, which substances undergo in their transit from the stomach to the organs of the body, in no example appears more strikingly than in that of organic salts. A vegetable acid, whatever be the nature of the base with which it is united, it is determined by repeated experiment, is transformed either in the blood, or at some stage of its passage from the stomach to the eliminating organs, into carbonic acid. In all

instances the presence of the base may be determined in the secretions; but the original acid is always found to be converted into the carbonic. By the experiments and analyses of Gilbert Blane and Wöhler, this conversion has been well established in the case of the citrates, tartrates, oxalates, and acetates. From the atomic composition of these acids, it may be readily shown that, in order to their complete transformation into carbonic acid, a considerable accession of oxygen must take place. Thus—

	O.	O.	H.		Ox.	
1 eq. citric acid=	4	4	2	would require	6 eqs. to convert it into carbonic acid=	4 eqs.
1 eq. acetic acid=	4	3	3	„	8 eqs.	„ =4 eqs.
1 eq. tartaric acid=	4	5	2	„	5 eqs.	„ =4 eqs.
1 eq. oxalic acid=	2	3	0	„	1 eq.	„ =2 eqs.

Since the proportion of carbonic acid thus formed is in every instance, with the exception of the last, considerably more than sufficient to neutralise the equivalent of the original base, it is certain that a large amount of this gas must be eliminated in the blood at the moment at which the conversion of the original acid is being effected. It cannot be doubted that the carbonic acid thus generated must render more complex the operation of the original salt. When this subject is considered by the exclusively chemical inquirer, the presence of this nascent agent in the blood is thought to contribute in no very important degree towards the production of the ultimate effects. In regard to the seat and cause of this conversion, Liebig very ingeniously conceives it to occur and depend upon that process of *eremacausis* constantly proceeding in the lungs, by the combination of the oxygen of the air with the elements of the blood. If this view be correct, it results that a considerable proportion of the oxygen absorbed in respiration must be appropriated to the conversion of these organic acids into the carbonic, rather than to the change of venous into arterial blood. It is not improbable that the “cooling operation” of these vegetable salts may have some dependence upon this inordinate appropriation of oxygen. This local combination happens also in the examples of all mineral acids; but the operation of an acid is essentially different, according to the state of concentration or dilatation in which it is given. In the former case it corrodes, by powerfully

and directly combining with the albuminous and fibrinous elements of the part of contact; in the latter its dilution precluding the corrugation of the walls of the stomach, or the parietes of the vessels, it passes unchanged into the blood, to combine with those of its elements, for which it possesses the most pointed affinity: if in minute proportion, the action of the compound which is thus generated in the blood will manifest itself in a *tonic* effect upon the general system, or, if given in larger doses, will operate as an irritant upon the spinal centre, and convulsions will supervene. It cannot be denied that the power of tannic acid would suffer considerable diminution by passage through gelatinous tissue. It is, on the contrary, fully determined that all the salts of the stronger alkaline bases, if not in too concentrated state, perform the circuit of the organic system, without suffering any change of composition. The chlorides, iodides, sulphocyanides, ferrocyanides of sodium and potassium, may be detected unaltered in the various secretions of the body. I may here incidentally remark, that I have succeeded, by properly adjusting the inflated lung of the salamander under the microscope, in detecting marked differences in the character of the capillary circulation, after the injection of any of these soluble salts beneath the integuments at any part of the body; the details of these observations will be presented in more matured form in my next communication. The few illustrations already adduced will be received as adequate to the esta-

blishment of the general fact, that agents which attain, undecomposed, the channel of the circulation, produce their characteristic effects, either by the formation of a definite compound with some of the proximate elements of the blood, or by their mechanical presence and influence in their insulated transit through the system. In the vegetable kingdom, numerous genera and orders of plants are found, of which the mode or principle of operation is so uniform and unvarying, that the active principle of each group may be stated to possess a definite relation to some one element or system in the organism. It is from this circumstance that the system of botanicaal classification first propounded by Jussieu, derives its most philosophic confirmation. The genera of the orders apocynaceæ, to which the upas, woorala and strychnine poisons belong, are as uniformly distinguished by the terrific rapidity and virulence of their operation, as those of the ranunculaceæ by their acridity and bitterness, or those of the genus papaver by the narcotism which attends their agency. In extending our survey further into the details of the subjects of which an imperfect outline only has here been offered, and regulating each succeeding step on the plain principles of physiology, the laws which determine the mode of an agent's operation upon the living system may be made to assume a character of considerable precision. From the preceding considerations, it appears to me that the method best calculated to conduct to useful and definite results in the study of this interesting but complex subject, should consist, firstly, in ascertaining the nature of the changes which substances undergo by contact with the contents and walls of the stomach and intestines; secondly, to determine the character and properties of the compounds formed by the combination of these agents with the elements of the blood, and the effects of these nascent combinations upon the several systems of the organism; and thirdly, to investigate the operation of agents upon the several departments of the nervous system—the cerebral, spinal, and sympathetic—by insulating, as far as practicable, each, for the purpose of experiment and observation, according, that is, to the plan recently so lucidly and masterly laid open by Dr. Marshall Hall.

Preparatory to further inquiry, it may be allowed me, in connection with this communication, to state the result of an experiment which recently suggested itself while investigating the subject of branchial respiration. In the breathing apparatus of the fish, two fluids are concerned, of different densities, and impregnated with different gases, on either side of the capillary parietes; on the internal, the blood charged with carbonic acid; on the external, the surrounding element holding in solution atmospheric air. On the well established principle of gaseous diffusion, notwithstanding the presence of a membranous septum, it will be admitted that the centric and eccentric currents of carbonic acid and oxygen, proceed in obedience to the law of which the expression is, that the diffusive power of a gas is inversely proportional to the square root of its density. But let it be conceived, that the more liquid portions of the blood, and the external water respectively, pass in intercrossing directions, into and from the vessels, would not the endosmotic forces of liquids oppose or modify the tendency to diffusion in the gases which respectively they held in solution? To determine this doubt, I contrived the following experiment. If, as indicated in the

annexed diagram, the small vessel *a*, be filled with *sugar-water*, which has been shewn by Dutrochet to be capable of producing an endosmotic current, with a comparative velocity of  $17^\circ$ , be impregnated with a small volume *a*, of atmospheric air, and properly adjusted upon a stand in the larger vessel *B*, the former being inverted, so that the interposed septum may be the lowermost part, and the vessel *B* filled with water charged with carbonic acid *b''*. I have succeeded in determining, first, that the superior force with which the sugar water is impelled in an eccentric direction, does not communicate a corresponding endosmotic velocity to the air with which it is impregnated; that, secondly, the centric current of the carbonic acid is not affected or neutralised by the opposing stream of the sugar-water, nor does the carbonic acid appear to impart any of its centripetal tendency to the water in which it is dissolved. In these observations it was

calculated that the endosmotic properties of carbonic acid and air are as 30 to 17. These numbers nearly correspond to the diffusive velocities of the gases. I am not aware that this double current has before been introduced into the principles of endosmosis. I do not announce this result as conclusively established, for upon a subject so involved by sources of fallacies, repetition and unusual care are the only guarantees of accuracy. On a subsequent occasion I hope to show that this, which appears to me as a new fact on the subject, will have an important application to the question of imbibition, and other properties of organic membrane.

9, Maze Pond, Borough.

#### CASE OF

### SPONTANEOUS PERFORATION OF THE STOMACH;

WITH OBSERVATIONS ON THESE AFFECTIONS GENERALLY.

BY JAMES B. THOMPSON, A.B. M.D. &c.\*

(For the Medical Gazette.)

MARIA MARTIN, ætat. 26, unmarried, of nervous temperament, previous good general health, and of very active habits, had never complained of any gastric derangement, and had been regular the previous month, was, when in the act of putting on her stays, suddenly seized with an acute pain in the region of the epigastrium: this was at eight o'clock A.M., and continued to increase hourly. Dr. Thompson visited her at 12, noon, and found her then labouring under the most acute, and seemingly excruciating pain, which she from her own account attributed to the stomach; and pointed out one part in particular, about an inch and a half to the left of the ziphoid cartilage. Leeches were at once directed to be applied to this part, and afterwards the cupping-glasses to be had recourse to, and the bleeding to be freely encouraged by stuping, and bran poultices, occasionally returning to camomile and poppy stupes, with some laudanum added to these. A hip-bath was afterwards directed, and the patient to remain in it for twenty minutes, when she was removed into bed,

and got an active aperient draught, followed by a sedative with morphia. The leeches, cupping, stupes, and bath, seemed to afford her very considerable relief; and the draught had operated twice during the day, after which she had some undisturbed sleep for about an hour and a half. The pain, however, returned again at 11 o'clock that night, and seemed to be considerably aggravated, and to occupy the greater part of the abdomen. She had been again visited at 2 o'clock A.M. next morning, when she was evidently rapidly sinking, and approaching to the comatose state. It was then for the first time that this patient's case was considered one of that nature under which it is here headed—namely, a spontaneous rupture of the coats of the stomach, and that the diffuse peritoneal inflammation then present was consequent on the extravasation of the fluid contents of the stomach into the peritoneal sac. She gradually got worse, notwithstanding every thing that could suggest itself being done for her, and died in or about thirty-five hours from the commencement of her attack.

There was some difficulty in getting the friends to admit of a post-mortem examination; however, they were persuaded to allow it; and in doing so, twenty-two hours after death, the following remarks were at the time noted down:—In the outward appearance of the stomach there was nothing to attract notice; but in opening it there was presented a generally inflamed surface; and on closely examining its parietes, there was found in the lesser curvature a somewhat oval opening in the mucous membrane. The submucous coat was also similarly perforated; but the opening in the serous coat was not observable on the outer surface at first sight: it was only to be recognised (unless very minutely inspected) by passing a probe from the opening in the mucous coat. It was a somewhat oblique slit, not exactly corresponding to the opening in the inner coats, which was somewhat oval, and presented the appearance as if "punched" through. There was near a pint of the fluid contents of the stomach in the peritoneal sac, which presented a very general and diffuse appearance of inflammatory action having previously existed. There was no further exami-

\* Read before the Medical Society of London.

nation of the body allowed, owing to the great anxiety of the friends, but this young woman seemed to be in every other respect a very generally healthy subject.

**OBSERVATIONS.**—The foregoing case is an instance of a very peculiar form of disease, and which seems to be confined to a point, and terminates in ulceration. The period of time varies from twelve to thirty-six hours, which was near about the time at which this case proved fatal. We hardly ever have an opportunity of seeing the stomach when this affection is commencing. Some are of opinion that it does not prove fatal during the early or inflammatory stage, as would appear to have been the case in the present instance. The ulcer itself does not often destroy life, but it permits the fluid contents of the stomach to pass into the peritoneum; and then it is the resulting peritonitis that proves so fatal. The ulcers in these cases are generally of various sizes, varying from the size of a sixpence, as was the case in this instance, to that of a half-crown piece. In the more chronic cases the ulcers are likely to be larger and better defined about the margin of the ulcerated part. They invariably are oval-shaped, or somewhat rounded, particularly on the mucous coats, and would present in the more recent cases the appearance already alluded to—namely, “punched out.” There is another remark which is generally noticed, and was observed in the preceding case; that is, that ulceration is mostly noticed in or about the lesser curvature, mostly on its posterior inferior surface.

It has been stated that these ulcerations are of a cancerous nature: but the author of the paper apprehends this must be a mistaken notion, and one that is contra-indicated by our present knowledge of cancerous affections generally; such cases as the foregoing, occurring most frequently in persons in the prime of life, and who have had no symptom of cancer about them. Besides, it is now very generally admitted, that cancerous affections are more frequently observed to occur in, and at, a later period of life. There is not that indurated feel, either, in the neighbourhood of these ulcerations, which the writer has noticed, and is so common and general an indication of the disease of cancer. The appearance

of the ulcer and its general history ought, in the author's opinion, to be a sufficient proof that it first had its origin in the mucous coat of the stomach, and not, as is invariably the case, in scirrhus affections in the sub-mucous tissue. Besides, there is more of the mucous coat destroyed in these cases than of any other membrane or tissue. The symptoms of these affections are at first rather obscure. In very many cases the general health appears good; often no complaint is made till some short time before death, when a most painful and violent train of symptoms present themselves. It would also appear, that the nerves and muscular coats are engaged at the same time with the mucous coat, and that it is only when the serous coat becomes engaged, that the symptoms just mentioned generally exhibit themselves. Then, either the peritoneal coat bursts, or rather *gives way*, and the contents of the stomach becomes extravasated, and a fatal peritonitis will ensue, or perhaps a degree of inflammation may be produced in a small portion of the peritoneum, which the ulcer has extended to, but not as yet destroyed; lymph is thrown out, and adhesions take place between that particular part and some adjoining viscus, and it is thus that life may be preserved for the time being. There is a remarkable case of this kind on record—that of the distinguished anatomist, Beclard. He died of a disease of the brain, and there was a cicatrized appearance observed about the lesser curvature, half an inch from the cardiac orifice; it was about the size of a shilling, its surface depressed and traversed by bands, one of which passed across the centre, and divided it into two lacunæ, whose base rested on the peritoneal coat. Recamier makes mention of a case in which the pancreas formed the base of a cicatrized ulcer of the stomach: the patient had died of another complaint. Cruveilhier, and others, do not consider such cicatrices of very rare occurrence.

Usually, however, the ulcer in these affections destroys life in one of three ways:—1st. By gradually exhausting the patient's strength, by pain, vomiting, and so forth, frequently aided by disease of the intestines, liver, spleen, or pancreas, with perhaps occasional dropsy: 2nd, by hæmorrhage, which is either the result of slow and often re-

peated oozings of blood from the ulcer, or may be more sudden from a large vessel, which the ulcer eventually opens; 3d, by the more quick and violent death which follows perforation of the stomach, and the consequent extravasation of its contents into the sac of the peritoneum.

In these suddenly fatal cases, the patient may be taken off in from *eight* to *twelve* hours, that is, before the inflammation has had time to have set in fully, and simply from the shock which the nervous system had sustained, and from which it cannot afterwards rally: this may be witnessed every day in the large public institutions of this great metropolis: in all cases of severe or extensive scalds or burns, or other similar very serious lesions or injuries; or a violent peritonitis, perhaps at first circumscribed, but soon becomes diffuse, and puts a period to the earthly career of the poor patient, in from twenty-four to thirty-six hours.

The diagnosis of ulceration is most difficult. Indeed, it appears to the author, that as yet we have not any pathognomonic symptom whereby we could distinguish this disease from other affections, such as gastrodynia, scirrhus, functional dyspepsia, chronic ulceration, or chronic inflammation. There is mostly vomiting and irritability of the stomach, but it has been seen without these. There is often pyrosis, and it also is often absent. In some cases a wasting of the flesh is remarked, but in others the "embonpoint" is retained. It would appear that persons remained in apparently perfect health up to the moment at which the ulcer gave way. Dr. Abercrombie gives a case of this kind, and another case is recorded in one of the Dublin Journals, of a young lady who went to church in excellent health, had never complained of any gastric disturbance, but was suddenly seized, while in church, with the symptoms of effusion into the peritoneal sac, and expired in thirty-six hours. The post-mortem, in this case, showed a perforating ulcer, with effusion and peritonitis. A circumscribed inflammation, which is perhaps more dangerous than a diffused one, because more apt to be followed by ulceration, may have only slight dyspeptic symptoms, or may even escape notice altogether, until the ulcer has perforated the stomach,

and then be followed by the fatal peritoneal inflammation. In the more chronic forms of these affections, the mucous membrane seems thickened, its papillæ considerably developed; the degree of redness varies in shades of colour from a dusky brown to a somewhat livid or leaden hue, often on detached surfaces or patches, here and there, where it would appear that ulceration would at some future period take place. A very interesting discussion followed the reading of this paper, after which the thanks of the society were voted to the author for his very comprehensive and practical paper. The society then adjourned to the 21st instant.

#### CASE OF HEMERALOPIA.

*To the Editor of the Medical Gazette.*

SIR,

If you think the following case worthy of notice, perhaps you will insert it in the MEDICAL GAZETTE.—I am, sir,

Your obedient servant,

J. THORNTON.

Holt, March 14th, 1842.

J. M., æt. 17, a healthy agricultural labourer, was attacked with hemeralopia last March. Vision was indistinct after sunset for a few days, gradually becoming more impaired, until total night-blindness ensued. His sight returned daily at sunrise, when he went out to his labour until the evening. During the blindness the pupils were much dilated, and uninfluenced by artificial light. He was blistered, and took alternate doses of mercury, with saline purgatives, for a period of five weeks, when his sight was perfectly restored, and has since continued perfect.

Night blindness is, I believe, rare in this country. It is not uncommon within the tropics, particularly in the region of calms about the equator, where the sea sometimes looks like glass for two or three weeks together, and reflects a vertical sun with great intensity. At these times sailors sleep on deck during their night watch, and hence the supposition that the moon strikes them blind.

The pathology of the complaint does not seem to be well understood. Is it a morbid condition of the retina from

congestion, or is it merely a periodical state of complete rest or insensibility, as a result of exposure to intense light? for the patients do not suffer any uneasiness, and their eyes are quite uninfluenced by bright artificial light.

### REMUNERATION OF PRACTITIONERS.

THE study of medicine is undoubtedly one of the noblest and most interesting subjects that can engage the mind; and its practice being essentially devoted to the alleviation of human suffering, and to the promotion of the general welfare, brings with it the highest satisfaction and pleasure. The practitioner is engaged in a work of universal beneficence, by which he becomes a friend to all; and on this account he may be regarded with a feeling of envy by those who view only this the bright side of the picture. But unfortunately these feelings of mental enjoyment, this consciousness of the utility of his avocation, can of themselves by no means supply the requisite *pabulum vitæ*, neither can they “cloy the hungry edge of appetite,” nor meet those demands upon his purse to which the medical attendant is necessarily subject. To these higher motives to energy and action, he, as well as those engaged in other pursuits, must add a mercenary view; and not only that, but he is obliged to use his utmost diligence to secure a fair and proper return for his services. It might have been supposed that to one thus engaged in forwarding the best interests of the community such a return would always be willingly tendered: a very little observation, however, shews

that this is by no means the case. The invalid just recovering from severe and dangerous sickness, is, perhaps, full of gratitude to the medical attendant, regarding him as the means of his restoration; but this short period of thankfulness past, all his good services are forgotten; the Christmas bill being regarded with horror, and paid with reluctance.

Herein, we are aware, consists one of the evils of the present system of dispensing practice, that it postpones the period of payment: still, in spite of this and other arguments adduced in opposition to it, we are inclined to esteem it, in a pecuniary point of view, as the method under which the practitioner derives a fuller emolument from certain classes of the community than he would obtain under any of the recently suggested schemes. The desire of having a *quid pro quo*, that strong propensity of the human character, is too powerful to be overcome by any ordinary reasoning, and must therefore be acceded to by the practitioner who looks to the lucrative end of his profession. The general mass of society are not content unless they receive some visible return for their money, and they estimate the ratio of their payment to the doctor, not by the assiduity of his attendance, or the skill he has manifested, so much as by the amount of medicine they have received. It is frequently suggested that, by this system, the profession is degraded, and that medical men, by thus dispensing drugs, lower themselves to an equality with tradesmen: it is, in fact, regarded by many as the great scandal of medicine. That this accusation does not hold good, is shown by the fact, that respectable practitioners are every where looked up to and esteemed; they maintain their proper level among the professional and scientific men of the place, and are admitted into society with them. Where this is not the case, and they

are placed below their proper position, we must not accuse the general system under which all act, but rather the mode in which it is in some instances carried out. If, for instance, the medical man, departing from his proper sphere, condescends to enter into competition with the retail druggist, or endeavours to gain practice by ungentlemanly rivalry with his brother practitioners, we cannot be surprised that he should meet with disrespect in the eyes of the world, or that he should, by this means, invoke an evil name on the whole class. We can call to mind instances in which medical men, more especially in country towns, suffer much from the low and disreputable practices of their brethren, who, by the sale of medicines at cheap prices draw away large numbers of patients. These, and other instances of a similar nature, are faults in the individual, not in the system; and we fear, whatever arrangements or alterations may be made, that opportunities will never be wanting for such black sheep to show themselves, and bring opprobrium on the profession at large.

The often-advocated plan of receiving fees for visits, instead of being paid for medicines, would, we grant, remove much that is disagreeable, and many opportunities of abuse; but at the same time it would also remove a great source of medical emolument. If brought into operation it would, we think, on this account, necessitate the retirement of many from the profession. Except in urgent cases the visits of the practitioner would be dispensed with; and often, in time of illness, would the prescription he had recommended on a previous similar occasion be again had recourse to, without incurring the additional expense of consulting him in person.

It has been proposed to affix certain standard prices to medicines, and with this view have been lately proposed

scales of charges for pills, draughts, &c. This system appears to possess scarcely any advantage, barely even to remove an abuse, the quantity of medicine to be sent being still necessarily left at the option of the practitioner, while it is open to many evident objections, which we have already alluded to in a previous number of our journal.

In Sir Robert Peel's new tariff it is proposed to reduce the duty on drugs, in some instances very considerably, especially on those which are the produce of our own colonies. It may, perhaps, be anticipated from this, that the charges of the practitioner for his dispensed medicines will fall in an equal ratio. This is by no means to be expected; the value of the drug as an article of commerce bears very little relation to the charge made for it as a prescription; the medicine is merely a medium by which remuneration is made for the time, the skill, and the labour of the medical man. As well might the lawyer be expected to diminish his fees on account of a reduction in the price of paper, pen, and ink, as the medical practitioner to lower his charges because the duty on drugs is diminished. We are indeed inclined to question the advantage of a cheaper sale of drugs to the public, inasmuch as it is likely to lead to their more indiscriminate administration; but we do not propose now to enter further upon that topic.

The economizing plans which the governments of the day, whether from necessity or not, have recently adopted, press upon no class more heavily than the medical practitioner. We may say with truth that their services in public appointments are less liberally repaid than those of any other persons. Their duties are highly important—their qualifications must be commensurate; their anxiety is great and harassing—their labour and assiduity require to be constant; and yet what a poor remuneration

ration do they receive for their services when paid by public authorities! The inadequate manner in which they are requited under the present poor law system is notorious. The ruling principle of that system is, by contract to reduce every thing to the lowest possible mart—a principle which is followed up by the guardians to its greatest extent, when the lives and health of the paupers under their charge are the subject of treaty. Taking advantage of the overstocked condition of the profession, and the all-compulsory threat of inviting from other places fresh men who may intrude upon the ground of the already existing practitioners, they bring the latter to their own terms, and force upon them the duties of a pauper practice, at a premium barely repaying the expenses necessarily incurred for drugs. In some cases it is totally inadequate even for that: as an instance, we need only allude to the advertisement inserted by a correspondent in a recent number of our journal, according to which, a medical officer was required to take charge of part of the North District of the Lincoln Union, including no less than fourteen parishes; the contract to include all necessary attendances in midwifery and surgical cases, with “all appliances and means to boot”—the salary for all this labour and attendance being the noble sum of £25. per annum.

We must not, however, omit to mention our satisfaction at finding some amelioration, in this respect, in the schedule recently issued by the Poor Law Commissioners, of which a notice was given in last week's *GAZETTE*, and in which we hope we may trace a glimmering of better things to come. Surgical operations and the treatment of fractures are made the subjects of separate and more liberal payment. A proviso is added with regard to surgical operations; but confining the payment

to those cases in which the patient survives thirty-six hours, which is, perhaps, objectionable, as it makes the surgeon's remuneration to depend rather too much upon the chances of life and death; besides which the difficulty and anxiety to the practitioner is usually greater in those cases which terminate fatally than in those which have a more favourable result. The attendant in midwifery is to obtain remuneration at the rate of from ten to twenty shillings in each case, and in difficult labours he is to receive £2, as the board of Guardians may determine. The last is a very important addition, as the attendance on midwifery forms a serious and heavy part of pauper practice, and is one which necessarily occupies much of the practitioner's time. We gladly welcome these concessions on the part of the commissioners, which we hope will before long be followed by a more liberal and general scheme for the remuneration of medical attendance.

#### PROPOSED CHANGES IN THE COLLEGE OF PHYSICIANS.

It has been stated in some of the public papers, that the constitution of the College of Physicians, according to the proposed new charter, is to remain as at present with respect to Fellows and Licentiates. We are happy in being able to state that this is incorrect, and that all who enter the College are to become “Members;” by whom and from among whom the Fellows are to be chosen. This is the kind of change we have often advocated in the *MEDICAL GAZETTE*; embracing, as it does, the abolition of the obnoxious appellation of “Licentiate,” and giving to all certain rights and privileges as *bona fide* Members of the Corporation.

#### FATAL QUACKERY.

*To the Editor of the Medical Gazette.*

SIR,

KNOWING the interest you have always shewn for the purpose of advancing medical reform and suppressing quackery, induces me to send you the following case for inser-

tion in some future number of your valuable Gazette.—I am, sir,

Yours truly,

JOHN MOYLE, Surgeon, &c.

Chacewater, Cornwall, March 18, 1842.

On Tuesday, the 1st inst., I was requested to visit Richard Bastian, a young man about 21 years of age, who, I was informed, had been unwell five or six weeks without seeking medical aid. On entering his bed-room, the cause of disease appeared to arise from the excessive or improper use of mercury, for a more intolerable stench (mercurial fortor) never assailed my olfactory nerves in any venereal ward.

He gave the following history of himself. Six weeks previously, and whilst enjoying his usual good health, he contracted gonorrhoea, for the cure of which he applied to a man called Wilkins (who had been a soldier, and who, I understand, has an extensive venereal practice), who gave him eight powders, four white and four yellow (I did not see them), with directions for taking them at stated intervals. In a short time his mouth became sore, and discharged abundantly for more than five weeks, when his friends became alarmed at what they considered to be a new train of symptoms, viz., sore throat and a rash, which led them to suppose he had scarlatina, but which proved to be ulcerated sore throat (with loss of hearing) and eczema mercuriale, for which his surgeon ordered him a light tonic and aperient.

I found him in the following state:—The countenance fallen, and expressive of mental misery; respiration hurried and deep; pulse small and quick; great depression of strength and spirits, with occasional fainting; pain of the stomach and bowels, with nausea and vomiting of a greenish-coloured fluid, diarrhoea and dysuria, the gums dark coloured and swollen.

Prescribed opiate and cordial medicines, with chloruret of soda gargle.

4th.—Countenance sunken and anxious; head constantly moving; talks incoherently; pulse very small and quick; respiration rapid; cough short, dry, and frequent; diarrhoea, lower gum and lip (which is perforated) sphacelated to the size of half a crown.

Continue the medicines and gargle; wine and water for drink.

He continued to sink until the evening of the 5th, when death put a period to his sufferings.

The quack, not satisfied with prescribing mercury internally for the cure of his gonorrhoea, recommended the application of Ung. Hyd. fort. to the scrotum (which was thickly plastered), and at least 3vj. of which I had taken from his pocket after death.

It was my intention to have had an inquest held on the body, and I wrote the

Coroner to that effect; but because the case did not amount to "*felony! but a high misdemeanor, the coroner would be overstepping the limits of his authority.*"

I cannot understand how a coroner in Cornwall has not the power to hold an inquest under such circumstances, whilst coroners in the eastern counties frequently hold inquests on the bodies of persons supposed to have died from the effects of Morrison's pills and other quack nostrums; or why, if legally qualified and eminent medical men are to be brought before metropolitan coroners' courts for *supposed* acts of mala-praxis (vide *MED. GAZ.* vol. ii. p. 875, 1839-40), a provincial coroner has not the power of holding an inquest on such a case as this.

This is the second case of cancrum oris terminating fatally from the effects of mercury, which has come under my notice within a short time; the first occurring in a female child a year and a half old, erroneously supposed (by a druggist who gave the medicine) to have had gonorrhoea.

## ATTENDANCE ON PAUPERS.

*To the Editor of the Medical Gazette.*

SIR,

I beg to enclose you a copy of a letter addressed by me to the Poor-Law Commissioners; with their reply, which you may insert or reject as you think proper.

Your obedient servant,

CHARLES COTTON.

Lynn, 5th April, 1842.

King's Lynn, 25th March, 1842.

*To the Honourable the Poor-Law Commissioners.*

GENTLEMEN,

I shall be much obliged by your informing me whether the treatment of fractures of the long bones, and dislocations, occurring in the Union house, are to be considered as operations, and, therefore, according to explanatory remarks upon article 10, not to be entitled to remuneration.

The injustice done under article 10, numbers 1, 2, and 3, to gentlemen holding the appointment of medical officers to the Union house, does appear to me most unfair; and it surely cannot be intended to make that injustice more oppressive by considering injuries embraced by numbers 4, 5, 6, and 7, of same article, as coming under the same class of objections and remuneration as those of numbers 1, 2, and 3.

Assuming the existence of hospitals and infirmaries throughout the country equal, and the governors of such institutions willing, to receive "patients who can be removed to the workhouse," or who "have long been subjects of treatment in the workhouse," nevertheless, severe accidents occurring in the Union house, requiring the skill and

most diligent attention of the surgeon, and "which cannot be sent to a public hospital" "with safety and propriety," are to be excluded from the rates of payment fixed "to secure proper attendance and medicine," and the poor unfortunate inmate to be deprived of the advice of an additional surgeon or physician, which is considered so necessary in the case of an out-door pauper, whilst a premium is offered to the surgeon having the charge of the out-door districts to endeavour to prevent cases of an extreme nature being sent to the hospital, where you say "paupers should enjoy the practised skill and combined judgment of the medical men usually connected with such establishments."—I have the honour to be,

Your very obedient humble servant,

CHARLES COTTON,  
Surgeon to the Workhouse and Infirmary, the  
Gaol, and one of the Surgeons of the West  
Norfolk and Lynn Hospital.

Poor-Law Commission Office, Somerset House,  
4th April, 1842.

#### *Medical Relief.*

SIR,

I AM directed by the Poor-Law Commissioners to acknowledge the receipt of your letter of the 15th ult., on the subject of the operation of the new medical order recently issued by the Commissioners, and I am to state that your observations shall receive the consideration of the Commissioners.

I have the honour to be, sir,

Your most obedient servant,

E. CHADWICK, Secretary.

Charles Cotton, Esq., Surgeon,  
King's Lynn.

#### CIRCULATION IN BRAIN.

*To the Editor of the Medical Gazette.*

SIR,

MY attention is directed by Mr. Bell, of Barrhead, to the experiments of Dr. Kellie, of Leith, on the circulation of the brain, which he thinks are opposed to views advanced in a paper on the effect of shocks on the head, inserted in your journal of the 25th of last month. I was not a stranger to these experiments, and I cannot see how they are in the least inconsistent with my views, nor has Mr. Bell been kind enough to point out how they are so; there is, therefore, need of no defence, for there has been no attack.

In the communication alluded to, the belief was expressed that aeronauts do not experience vertigo and many other symptoms, to which those ascending high mountains are liable; proving that some shock, to which the latter are exposed and the former not, is necessary for their production. It is gratifying to find a confirmation of the above statement in Dr. Holland's interesting

and instructive Medical Notes and Reflections. He says, "the observations in ascent by balloons show, even unexpectedly in degree, the extent to which the body can undergo the most sudden changes of atmospheric weight, without any very obvious effect, where the health is unimpaired, and no causes of bodily fatigue are conjoined." For "no causes of bodily fatigue," I would substitute the word *shocks*. Mr. Green, the celebrated aeronaut, expressly mentioned to Dr. Holland, that in "no instance have his companions experienced vertigo or sickness;" and yet Mr. Green and his companion Mr. Bush, attained the height of 27,136 feet, or 5 $\frac{1}{4}$  miles, at which the barometer stood at 11 inches, indicating little more than one-third of the ordinary atmospheric pressure at the level of the sea.

In considering the effects of diminished atmospheric pressure upon the brain, we must not forget the elastic form of vapour, which might arise from the surface of the brain, and which, supposing its temperature at 98°, would be equal to 1.7 inches of mercury; so that the pressure upon the brain when the barometer stood at 11, would be 9.3 inches only; a pressure, one would think, easily overcome by suddenly communicating momentum to the brain, or suddenly arresting it.

It is hardly necessary to say, that the brain feels the direct effect of atmospheric pressure whenever blood-vessels or nerves escape from the skull; that is, whenever there is absence of bone, and that this pressure is diffused unimpaired throughout its whole mass, causing the surface of the brain to press upon the dura mater with a force equal to 15lbs. to the square inch under ordinary barometrical conditions.—I have the honour to be

Your obedient servant,

THOS. HAWORTH, M.D.

Bolton, March 23, 1842.

#### ON PROSTITUTION IN THE CITY OF LYONS.

AMONG the causes of the frequency of prostitution and syphilis at Lyons, Dr. Potton particularly insists on the increase of population, which has chiefly taken place in the working classes. There are nearly 200,000 inhabitants in Lyons; of these, the working classes amount to 90,000. They are all young, most of them unmarried; and there are six women to five men, while it is proved that celibacy and prostitution keep an equal pace together.

The political disturbances which have agitated Lyons, and produced such frequent stoppages of work, the lowering of wages, which has especially affected the women, and inclined them to prostitution as a means of existence; distress, in short, has brought many of the prostitutes of Lyons to their

present state. The most usual of the physical causes, according to Dr. Potton, are suffering and hunger; of the moral causes, the most general are, the obliteration of family feelings, the want of religious ideas, inclination to evil, example, and improvidence. He also points out the faulty arrangements, by which working persons of both sexes at Lyons, are placed in the same workshops. The health as well as morals of the public are dreadfully affected by this promiscuous assemblage of the sexes.

Dr. Potton reckons the number of prostitutes in Lyons at 4400, which is about one in 50 of the whole population, or one in 25 of the female portion. Moreover, the author does not include those public prostitutes whose names are registered at the Mayor's, but those only who, not having lost all feeling of modesty, endeavour to conceal their frailty.

In a second part, the author examines the influence of prostitution and syphilis on the health, the habits, the work, and the well-being of the public. He shows that syphilis is injurious to public welfare by its own symptoms, by the morbid phenomena which are its result, by the changes of structure which it produces in the frame, by the disorderly life which accompanies or follows it in the working classes, by the suspension or diminution of work, and by the expenses which it causes.

The third part is devoted to an examination of the state of the charities of Lyons. There is but one establishment at Lyons where syphilitic patients are received, and that is far too small. It can receive only a very limited number of patients, of whom some are maintained at the expense of the town, while others pay for themselves. There are 85 beds, for girls of the town, poor women, and Lyonnese workwomen, sent there by the municipal or departmental authorities; twelve places are reserved for women who pay and enter at their pleasure. There is only one ward, containing from 25 to 30 beds, for men suffering from syphilis, and treated at the expense of the town or the neighbouring departments. An infirmary capable of containing 28 or 30 patients, receives men who pay. Thus, out of 160 places for venereal patients, 110 only are gratuitous, the others being paid for at the rate of 1fr. 25 cents. (one shilling) each daily. The number of beds is too small, and there is also a want of classification. The authorities have forgotten the words of M. de Gérando:—

"The respect due to poverty and misfortune requires us to distinguish between girls who are ill from debauchery, and innocent victims. Morality suffers from their being brought together; and they should be classed according to the greater or less

degree of corruption prevailing among them."

At the *Hospice de l'Antiquaille* at Lyons, this separation does not take place: and prostitutes who have lost all feeling of shame are mingled with unfortunate women, and girls seduced, but not lost beyond all hope.

The *surveillance* exercised by the police is also insufficient. It is only extended over 280 registered girls, a great number of whom entirely escape it. They are visited but once a month, the day and hour being previously fixed; so that the mistress of the house can easily withdraw those who are diseased, and substitute others who have nothing to fear from examination.

In the last part, the author gives his opinions on the means of lessening the ravages of prostitution and syphilis in the city of Lyons. He sets forth a thousand reasons for a radical reform in the employment of the means at the disposal of the police, and demands more serious efforts on the part of the municipal government for the increase and improvement of their charities.

(Abridged from a review of a prize essay by Dr. M. A. Potton, in the *Gazette des Hôpitaux*.)

## SCIRRHUS OF THE PANCREAS.

DR. MOLLAN exhibited the recent parts in this case; they were taken from the body of a man aged seventy-three, who had been admitted into the Whitworth Hospital, on the 28th of the preceding month. He stated, on admission, that he had been for a long time subject to pain in the stomach after eating, and that within the last six or eight months this pain had become severe and of frequent occurrence. He was considerably emaciated. He had tenderness on pressure over the epigastric region, and a tumor was perceptible, also, to the right of the umbilicus. No advantage was derived from any plan of treatment, and the man gradually sunk and died on the preceding Wednesday. About fourteen days before his death he became universally jaundiced, but had no vomiting until two or three days before death. He had been of temperate habits. On examining the stomach it was found distended with dark-coloured fluid, and its mucous coat presented marks of increased vascularity. The seat of the tumor was found to be the pancreas, the head of which appeared to be changed into a scirrhus structure; the termination of the biliary and pancreatic duct was compressed by it; the gall bladder and hepatic ducts were greatly distended with bile of a dark-green colour; there were several tubercles in the substance of the liver, of a white colour and scirrhus structure. — *Dublin Journal of Medical Science*.

A MALTESE MEDICAL JOURNAL

We have received two numbers of a medical journal published at Malta, which has been established about a twelvemonth. It is called *Il Filocamo, Giornale Medico-scientifico e di Educazione*, and appears twice a month. The two numbers before us are of the dates Dec. 16, 1841, and Jan. 15, 1842, each consisting of eight pages quarto. The one of January the 15th contains an article on the treatment of fractures in the civil hospital at Valetta; cases taken from the internal *clinique*; an examination of Clot Bey's work on the Plague; and an extract translated from the American Medical Intelligencer. The following is a table of the fractures treated under the direction of Dr. G. P. Portelli, principal surgeon on the men's side, during 1841:—

	No.	Discharged.		Died.
		Cured.	Under treatm.	
Leg	15	15	-	-
Forearm	13	11	1	1
Clavicle	6	5	1	-
Ribs	5	4	1	-
Thigh	3	2	-	1
Shoulder	1	1	-	-
Patella	1	1	-	-
Parietal bone	1	-	-	1
Total	45	39	3	3

The number for December the 16th contains, among other things, an account of operations for the cure of an inguinal hernia, of a hydrocele, and for the extirpation of an exophthalmos, performed by the pupils in the clinical ward, under the inspection of Professor Galland.

The publication of this journal does credit to our fellow-labourers in Malta. We wish it all possible success.

CARIES OF THE OCCIPITAL BONE.

DR. KIRKPATRICK exhibited a specimen of disease affecting the membranes at the base of the brain, attended with caries of the occipital bone, without any prominent symptoms during life. The patient was a poor woman who had been in many hospitals, and was admitted about a month since into the North Union Workhouse, with a large bed sore on her hip. With this exception she did not complain of anything beyond mere debility, and the treatment was directed to the restoration of her strength, and the cure of the ulcer; she remained, however, in the same state, and after some time she was attacked with occasional vomiting, and complained of pain in the back of her head; she had no paralysis or convulsive motions; she became gradually worse, and died a few days since, without

any prominent symptoms. On examination, the left lobe of the cerebellum was found to adhere closely to the membranes, and the latter were separated from the bone by a quantity of lymph: where the lymph lay in contact with the bone the internal table was eroded to a considerable extent. On examining the internal ear, it was discovered that the membrana tympani was absent, but the ossicula were still in their places, and there was no disease in the mastoid cells.—*Dublin Journal of Medical Science.*

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, April 1, 1842.

J. T. Fletcher.—A. Gillot.—M. A. Jane.—F. Southam.—W. Row.—William Mitchelmore.—J. Pegge.—W. Pocock.—M. Hudson.—P. M. Pope.—J. Dunn.—A. J. Cumming.

A TABLE OF MORTALITY FOR THE METROPOLIS,

Medicine and the Collateral Sciences.

FRIDAY, APRIL 15, 1842.

LECTURES  
ON THE  
PRINCIPLES AND PRACTICE OF  
PHYSIC,

*Delivered at King's College, London,*

BY DR. WATSON.

*Diarrhœa. Sporadic Cholera. Epidemic Cholera.*

THE morbid *fluxes* which proceed from the long tract of mucous membrane that lies between the stomach and the anus are many in number: and they vary much, both in kind and in cause. *Hæmorrhages* are not uncommon. I have already described the disease called *melæna*, which is characterized by the discharge of black semifluid matters, resembling tar, from the bowels, and in most instances from the stomach also by vomiting. The matters vomited, and the matters passed by stool, are composed principally of blood, which has been rendered black, and otherwise modified in appearance, during its progress outwards in the one direction and in the other. Again, hæmorrhage from the bowels is apt to occur in *continued fever*; as I shall shew you when we come to that disease. Hæmorrhage takes place also from the rectum in *hæmorrhoids*, or *bleeding piles*: a malady that falls chiefly to the care of the surgeon. Blood comes away too, mixed with a greater or less quantity of mucus, in *dysentery*.

The remaining forms of profluvia from the intestinal canal I shall proceed to consider *seriatim*; at least the most important of them.

*Diarrhœa*.—There are several very different affections classed together under the head of *diarrhœa*: by which term is usually signified the occurrence of frequent, loose, or liquid alvine evacuations. Thus diarrhœa

is a very common symptom of pulmonary phthisis; and this form of the disorder has been already mentioned. It is very often met with also in continued fever, and during the decline of the febrile exanthemata, of which I have yet to speak. But diarrhœa is not unfrequently the main symptom of the disorder under which the patient labours; and constitutes, at any rate, the chief object of our treatment. I shall touch briefly on some of its varieties.

In the first place, there is that common form of the complaint which proceeds from over-repletion of the stomach; or from the ingestion of food that is not wholesome: food that disagrees (as the phrase is) with the patient's stomach and bowels at that particular time. We may call it, with Cullen, by way of distinction, *diarrhœa crapulosa*; in which fæces are discharged in a more liquid state, and more copiously, and more often, than is natural. These cases are in truth slight cases of irritant poisoning. The ingesta irritate the mucous surface, and probably the muscular coat also; the secretions of the inner membrane are poured forth in unusual abundance, and the peristaltic motion of the intestines become more strong and active; the objects of these changes being that of getting rid of the offending substances: a salutary and conservative effort, which we assist and imitate in our *treatment* of this form of diarrhœa.

The symptoms by which this species of diarrhœa is marked, must be well known to us all. There are often nausea; flatulence; griping pains in the bowels, succeeded by stools of unnatural appearance and odour, and of fluid or watery consistence. There are often, also, a furred tongue and a foul breath: but the disorder is attended with little or no fever; the pulse remains of the ordinary frequency; and the temperature of the body does not rise.

There are certain things which, more than others, tend when taken into the stomach to cause this crapulous diarrhœa: and there are

certain circumstances which increase the disposition to be affected by the ordinary exciting causes.

We frequently see this disorder supervene upon a debauch, in which case the *mixture* of various articles of food, and of drink, each of which in itself might have been perfectly innocent—and the actual *quantity* of the mixed ingesta—have occasioned the irritation and disturbance. But where there has been no intemperance in eating or drinking, some kinds of food are more likely than others, *ceteris paribus*, to provoke diarrhoea. I do not speak of idiosyncrasies, which show the truth of the old proverb, that what is one man's food is another man's poison, and which cannot be reckoned upon beforehand; but I refer to the average of systems and stomachs. And among these indigestible and irritating substances we may place *raw vegetables* of many kinds; such as cucumbers and salads, sundry kinds of fruit, especially if they be immature and acid, plums, melons, pine-apples, nuts, and so forth. Mushrooms may be added to the list, even when they are cooked. *Putrid* food, or food which, in the more refined phraseology of gastronomers, is termed *high*, has the same effect upon some persons: and so, in a particular manner, have some kinds of *fish*; shell-fish, crabs, and muscels, for instance, in this country; and in other countries, in the West Indies, there are several species of fish which are actually poisonous, and cannot be safely eaten at all. A similar disorder is frequently produced in children by any sort of food, other than the natural sustenance furnished by the mother. The new kind of nutriment disagrees with them: and the very same thing is apt to occur in adult persons. An article of diet which is perfectly wholesome and digestible, and which the stomach bears well after a little habit, will sometimes cause griping and purging, when it is taken for the first time. It is upon this principle that the diarrhoea to which Englishmen are subject upon their first visiting the towns upon the continent, is to be explained. I do not know that it is so, but I think it very likely that Frenchmen, and Germans, and Italians, suffer in the same way when they first come to this country, and adopt our habits and regimen.

Another curious exciting cause is to be found in certain *mental emotions*, and especially the depressing passions: grief, and, above all, fear. A sudden panic will operate on the bowels of some persons as surely as a black dose, and much more speedily. Among the circumstances which *predispose* most persons to this kind of malady, we may particularly specify *season*—the hot weather of summer and autumn. And it is probably consistent with the experience of

most of you, that the atmosphere of the dissecting-room has a similar tendency.

Now this diarrhoea, from occasional irritation, produced by the presence of substances that offend the stomach or bowels, will generally cease of itself. The purging is the natural way of getting rid of the irritant cause. We may *favour* the recovery by diluent drinks, and by making the patient abstain from all further use of food which is not perfectly easy of digestion; and we may often *accelerate* the recovery by sweeping out the alimentary canal by some safe purgative, and then soothing it by an opiate. Or we may give the aperient and the anodyne together, and the one will not interfere with the operation of the other. A table spoonful of castor oil, with six or eight minims of laudanum dropped upon it: or from fifteen grains to a scruple of powdered rhubarb, with half as much of the *pulvis cretae compositus cum opio*. By some such medication as this, emptying the bowels, and quieting them, the cure is generally accomplished with ease, and speedily:  *tuto, cito et jucunde*.

We sometimes however meet with cases in which diarrhoea *runs on*: the stools being composed of fecal matter in an unnaturally fluid state; and the precise condition on which this disposition to an overloose state of the bowels depends, escaping detection. If the disorder be slight, it will often yield to the astringent and bitter medicines. The infusion of cuscuta, and the tincture of cinnamon, supply a convenient formula. If it be more severe, or obstinate, we have recourse to chalk mixture, which neutralizes acidity; combined with catechu, which is a direct astringent of the tissues; and with laudanum, which calms irritation. And in extreme cases the sulphate of copper has been found to have a powerful effect in restraining the flux. It is apt to gripe, and should be combined therefore with opium. A quarter of a grain of each, in a pill, given three or four times a day, I have frequently found successful, when previous attempts to remove the diarrhoea had failed.

*Sporadic cholera*.—I have alluded to the influence of *hot weather* in predisposing the system to be affected by the exciting causes of diarrhoea. And there is a complaint, of which diarrhoea is one prominent symptom, but which is something more than mere diarrhoea, that shows itself in this country, more or less every autumn, and prevails extensively in some years, as a minor epidemic. It is rightly enough named *cholera*; for it is attended with, and consists mainly of, a remarkable flux of *bile*. Sydenham held that the disease is limited to the month of August; and that bowel affections, with

vomiting, occurring at other times, are not genuine cases of cholera. But this was one of that great man's crotchets. The symptoms that mark this complaint are vomiting and purging of liquid matter, deeply tinged with, and principally composed of, bile; violent pains in the stomach and bowels; cramps of the legs and of the abdominal muscles; a great depression of the vital powers, and a tendency to syncope or collapse.

The attack is generally sudden. At first the contents of the alimentary canal are evacuated; and then a quantity, an enormous quantity sometimes, of a turbid, yellowish, acrid fluid, is expelled with violence both from the bowels, and by vomiting. The patients complain of a burning sensation in the epigastrium. As the vomiting and purging go on, tonic spasms of the lower extremities, and especially of the gastrocnemii, occur; the surface of the belly is drawn up into knots: and after a while, the patient, exhausted by the pain and the spasms, and still more so by the copious discharges, grows cold, and faint. Sometimes actual syncope happens: and sometimes death.

Death, however, is an uncommon event of this form of cholera, in this country.

The chief cause of cholera, such as has now been described, appears to be casual exposure to cold, after a continued high temperature of the atmosphere: and the great irritation of the stomach and bowels evinced by the symptoms, proceeds from the presence of bile in the intestines in undue quantity, and rendered more acrid than usual by some morbid alteration of its quality. The attack seems to be often determined by some of those causes of irritation which I just now mentioned when speaking of simple diarrhoea; and particularly by imprudence in eating and drinking.

I believe that no better treatment can be followed in this disease than that long ago laid down by Sydenham. He observes that any attempt to stop the purging and vomiting by strong drastic aperients, under the notion of expelling the irritant matter, would be like endeavouring to extinguish fire by pouring oil upon it; and that to try to lock up the acrid discharges in the alimentary canal by means of narcotics or astringents, would be equally hurtful. He therefore was accustomed to dilute the contents of the stomach and bowels by emollient drinks, and injections, especially by chicken broth; and so to favour their expulsion: and when any faintness or sign of sinking began to shew itself, to administer laudanum in full doses. We are seldom summoned to these cases in the outset. Generally the vomiting and diarrhoea have continued for some hours before we see the patient; so that it is expedient to give the opiate as soon as we can.

If the stomach be very irritable, solid opium in the form of pill may be preferable to laudanum; or an opiate clyster—or an opiate suppository—may be introduced into the rectum. When the skin is cold, and the pulse sinking or irregular, carbonate of ammonia, or brandy and water, may be given by the mouth; and a mustard poultice, or a bag of hot salt, or a moist and hot flannel sprinkled with oil of turpentine, should be applied to the abdomen. The cramps of the extremities may be relieved by diligent friction with the hand; or some stimulating liniment may be rubbed upon the affected muscles. When the collapse is great, the patient should not be allowed to raise himself out of the horizontal posture, lest fatal syncope should occur. Opium, however, is our sheet-anchor in this complaint: it sustains the flagging powers, while it quiets the gastro-intestinal irritation.

After an attack of severe cholera, the patient is apt to be left extremely feeble; with soreness of the muscles of the trunk and limbs: and sometimes symptoms of inflammation of the mucous membranes will supervene; pain and tenderness of the belly, a white tongue, thirst, and fever. And these symptoms may require some of the remedies of inflammation.

*Epidemic Cholera.*—Such is the disease which had long been familiar to English practitioners, as *cholera*: but between ten and eleven years ago, this country was visited by a severe epidemic disorder, which was also called cholera; or by way of emphasis, *the cholera*; or sometimes *spasmodic cholera*; or *Asiatic cholera*; or *malignant cholera*. The symptoms of this new disease resembled, in some points, those of the old-fashioned cholera: but differed from them in more, and in more important, particulars. So that the application of the term cholera, or cholera morbus, to both these morbid affections, is very much to be regretted, for it has produced a great deal of confusion and inconvenience.

I scarcely know how to name the newer and severer disorder. I have no right to alter the received nomenclature; and choosing from among the many appellations which have been applied to the complaint, that epithet which seems the least objectionable, I may call it *epidemic cholera*: although this term is objectionable, since the other form, the *English or sporadic cholera*, is sometimes also epidemic.

The *epidemic cholera* so far resembled the *sporadic*, that it was attended by profuse vomiting and purging, by extreme prostration of strength, and by cramps. But it differed remarkably in these respects; in the circumstance that the matters ejected from the stomach and bowels contained no bile

(and this alone is a good reason against calling the malady *cholera*); in the early supervention of the symptoms of collapse; and in the great mortality of the disorder.

The amount of the fluid matters thrown up from the stomach and discharged by stool, was really in many cases wonderful. At first, perhaps, the patient would have so copious a stool—a consistent dejection it might be, but so large in quantity—as to lead him to conclude that the whole contents of the intestines had been evacuated at once. Yet soon afterwards a turbid whitish liquid would again and again pour from his bowels in streams; and be spouted from his mouth as if from a pump: not in general with much effort, but easily and abundantly. The matters thus discharged were thin, and for the most part of a whitish colour, like water in which rice has been boiled; without fecal smell; and containing small white albuminous flakes. There were some varieties in the evacuations, but the kind I have mentioned, resembling rice-water, were the most common and the most characteristic: and however *else* their sensible qualities might vary, *this* circumstance was universal, that they contained no *bile*.

With all this there was early sinking, and collapse, as it was called. This term *collapse* expressed a general condition, made up, in the most exquisite cases, of the following particulars:—A remarkable change took place in the circulation, and a striking alteration in the appearance of the patient. The pulse became frequent, *very* small and feeble, and at last, even for hours sometimes, extinct at the wrists. The surface grew cold; and in most, or in many instances, blue as well as cold. The lips were purple; the tongue was of the colour of lead, and sensibly and unpleasantly cold to the touch, like a frog's belly; and the breath could be felt to be cold. With this coldness and blueness there was a manifest shrinking and diminution of the bulk of the body. The eyes appeared sunk deep in their sockets; the cheeks fallen in: in short, the countenance became as withered and ghastly as that of a corpse. The cadaverous aspect that sometimes precedes death in long-standing diseases, would come on in the course of an hour or two in this complaint. If the physician left his patient for half an hour, he found him visibly thinner on his return. The finger nails became blue; the hands and fingers shrivelled, white, corrugated, and sodden, like those of a washer-woman after a long day's work. The skin was bathed in a cold sweat. The voice became husky and faint. So peculiar was this change, that the sound was spoken of as the *vox cholericæ*. These are the symptoms which the single word *collapse* was meant to express.

Another very striking feature of the disorder was the muscular cramp; affecting the muscles of the thighs and calves of the legs, rendering them as hard and rigid as wood; and drawing up into lumps the muscles of the abdomen. These spasmodic contractions were attended with severe pain, and constituted the greater part of the patient's suffering. During the continuance of the symptoms that I have been endeavouring to describe, not a drop of urine was passed or secreted. One man, who was under my own observation and care, and who recovered, did not void a drop of water from Sunday morning till the afternoon of the following Wednesday.

Even in the extreme state of collapse the intellect remained quite clear: the patients would continue to talk rationally to the last moment of their lives; and, for the most part, they seemed singularly indifferent and apathetic about their condition.

In the fatal cases—and a very fearful proportion of the whole number *were* fatal—death took place sometimes in the course of two or three hours; and it was seldom delayed beyond twelve or fifteen. In those that recovered, the favourable symptoms were the cessation of the vomiting, purging, and cramp; the return of the pulse, and of warmth to the surface; the disappearance of the blueness of the skin, and of the hippocratic countenance; the *re-appearance* of bile in the alvine evacuations; and the restoration of the secretion of urine.

The course of the symptoms varied a good deal in different persons. Sometimes the vomiting and purging soon ceased; and sometimes there was neither sickness nor diarrhoea at all, but rapid collapse and sinking. These were thought the most formidable cases. However, the peculiar secretions were *poured forth*, in some, at least, of the instances in which none of them were *ejected from the body*. A patient died of cholera in the Middlesex Hospital without any vomiting or purging: but on examining the dead body, we found the intestines quite full of the rice-water serous fluid. Sometimes the cramps were not very troublesome. The cutaneous blueness was not a universal phenomenon. The patients were in general tormented with thirst: and when attempts were made to bleed them, the blood was found dark and thick, like treacle, and scarcely moving, if moving at all, in the veins: in some cases it could not be made to flow out. Considerable hurry and anxiety of the breathing were also symptoms that I omitted to mention before.

The examination of the dead bodies threw no light, that I know of, upon the nature of this frightful disease. The alimentary canal generally was found to contain a white liquid, having white flakes in it; such as had pre-

viously issued from the bowels: and the mucous glands of the intestines, both the solitary and the agminated, were unusually large and conspicuous. The veins were loaded with thick, black, tar-like blood; and the urinary bladder was always found empty, and contracted into the size of a walnut. Even when the blue colour had existed in a marked degree during life, it often quickly disappeared after death. And another most singular phenomenon was occasionally remarked in the dead body. A quarter, or half an hour, or even longer, after the breathing had ceased, and all other signs of animation had departed, slight, tremulous, spasmodic twitchings and quiverings, and vermicular motions of the muscles, would take place; and even distinct movements of the limbs, in consequence of these spasms.

The disease, of which I have drawn but a faint outline, was not known in this country till the autumn of the year 1831. There are persons, I am aware, who hold that it has always existed among us; only not in such numerous instances as at that period; and they appeal to Morton, and other early writers on the diseases of this country, in support of their opinion. But the malady was too striking to be overlooked, or ever forgotten, by any one who had once seen it. Certainly, till that year I never saw any thing like it. To be sure I had not at that time been very many years in practice here. The late Dr. Babington, however, told me that it was quite new to him. He had, for a very long period, been in extensive practice, in those parts of the metropolis and its vicinity where the epidemic cholera raged most; and when it first came among us he had the curiosity to ask every medical man whom he met, whether he had seen any case of the cholera; and if the answer was "yes," he went on to enquire whether, before that year, the person had ever met with the same complaint; and the reply was always, without a single exception, "no." Yet I say there were, and are, a few practitioners who denied, and deny, that it was any thing more than the common and well-known English complaint raging with unusual frequency and violence.

But we have evidence of a different kind of the newness of the epidemic cholera to these kingdoms. Its approach was discerned afar off, as distinctly as a storm is foreseen by the rising of the clouds from the horizon in the direction of the wind. The disorder began to rage with terrible severity, in India, in the year 1817. I do not mean that it then broke out there for the first time. It had visited those regions again and again before. But from its irruption in the year I have mentioned, when it committed frightful devastation in the armies in the north-

eastern districts of India, its course can be distinctly traced to our own shores; towards which it approached with slow and halting, but with sure steps, in a north-western direction. From India it spread to Persia; and thence to Russia; and across through Poland to Germany: and at length it was found at Hamburgh. It was predicted before that time, that the distemper *would* at length reach Great Britain. Our government had even sent two physicians into Russia to investigate its nature, in the fearful anticipation that its march across the earth would continue progressive; and accordingly, at the expiration of fourteen years, it made its appearance on the *eastern* coast of this country; in Sunderland: and in due time extended over every part of these islands. I say its arrival had been *foreseen* and *foretold*; and it is absurd to suppose that a vast number of persons would fall sick, and die, with symptoms quite strange to the great mass of practitioners here, merely to fulfil this prediction.

The progress of the disorder did not end here. Crossing the Atlantic, it invaded America; turning, at the same time, in a south-easterly direction, it ravaged France and Spain, and the north coast of Africa, and Italy.

Moving thus onward, as it did, in defiance of all natural or artificial barriers, under opposite extremes of temperature and climate, in the teeth of adverse winds, over lofty mountain chains, across wide seas, through "hot, cold, moist, and dry"—in what manner, you will probably ask, was this wasting pestilence *propagated*?

Upon this point various and discordant opinions are entertained. Many persons believe that the complaint spread by contagion: more, however, that it was not contagious at all, but arose from some deleterious cause with which the general atmosphere of the place was pregnant. Now I cannot reconcile the phenomena of the appearance and extension of the malady with either of these hypotheses *exclusively*. It must, I think, be granted, that the complaint, in every instance, was excited by the application of some noxious material to the body, some positive poison. It is certain, also, whichever hypothesis may be chosen, that many more individuals were exposed to the agency of this poison, than were injuriously affected by it. This exemption from the disease no more invalidates the doctrine of contagion, than it invalidates the doctrine of some diffused atmospheric influence: nay, it is more explicable upon the former than upon the latter supposition; for while many may avoid a specific contagion, all are immersed in, and all breathe, the common atmosphere. But the exemption shows *this*; that the exciting cause, to

be effective, required a fit recipient: that the susceptibility of being hurt by the poison in its ordinary dose and intensity varied much in different persons; and in the majority was very faint, or wanting. It is clear that the poison travelled. It is equally clear to my mind, that it was *portable*; and therefore communicable from person to person. I even believe that it was capable of being conveyed, and was actually conveyed, from one spot to another, by persons who were themselves proof against its effects. The innumerable authentic instances of coincidence, in point of time, between the first outbreak of the disorder in a particular place, and the arrival at that place of some person or persons from an infected locality, prove that the poison could be thus carried. Whether the malady was contagious in the same sense in which small-pox is contagious—whether, I mean, the cholera poison had the power of multiplying and reproducing itself in the human body, as yeast multiplies itself during the fermentation of beer—is a different and a much more doubtful question. A disorder may be contagious, without this property of reproduction in the animal fluids. The itch is contagious. The itch is produced by a minute parasitic animalcule, whose existence has, of late years only, been assured to us by the microscope. Suppose that these itch insects could fly, or were capable of being wafted through the air—they would then represent what is conceivable enough of the subtle exciting cause of cholera. Between the two epidemic distempers, influenza and cholera, there were numerous and striking points of similitude or analogy. They have observed the same, or very nearly the same, geographical route. Both, issuing from their cradle in the east, have traversed the northern countries of Europe, till, arriving at its western boundary, they have divided into two great branches; the one proceeding onwards, across the Atlantic, the other turning in a retrograde direction, towards the south and east. The main differences between them have been, that whereas the poison of influenza spared very few of the community, inflicting a disease which, of itself, was seldom fatal—the poison of cholera, on the contrary, smote very few, but with so deadly a stroke that as many sunk beneath it, probably, as recovered. Both were *general* disorders, affecting the whole system, but in both the most prominent of the symptoms had reference, in the majority of cases, to the mucous membranes: to those of the air-passages in the influenza; to those of the alimentary passages in the cholera.

Now this strong analogy has been made use of as an argument that the cholera was not contagious. “The influenza (say the objectors) had no contagious properties;

therefore it is, *a priori*, likely that the cholera had none.” But I demur to the major proposition. Cullen thought the influenza was contagious, and I adverted, in a former lecture, to some facts which favour that belief. Supposing it, however, to be so, the proof of its contagious property must, from the very nature of the case, be extremely difficult. Its visitations are so rapid, widely spread, and multitudinous, that there is no time for its transference from house to house, or from person to person: yet it may be nevertheless transferable. Its inherent rate of locomotion outstrips and precludes the tardier conveyance of the poison by man. Its contagious qualities (granting them to exist) are hidden in its universality, and can seldom be traced but by accident. I therefore esteem this argument from analogy as worthless; and my own creed respecting the cholera is, that it *was* contagious, in the limited sense already explained; but that its contagious power was not very great: that a comparatively small part of the population, of this country at least, was susceptible of its operation; and that few were in much danger of suffering from exposure to the physical cause of the disease, except under circumstances of predisposition. At the same time I believe that a great majority of the cases of cholera were not attributable to direct contagion, but to the poison diffused through the atmosphere. There is nothing inconsistent in the supposition that this noxious matter travelled sometimes by its own peculiar powers, sometimes made use of vehicles.

This, I say, is my creed upon the vexed question of contagion. Respecting the special nature of the poison I can only guess; and my guessing, as you may have perceived, takes the same direction as before. I adverted, when speaking of the influenza, to what Dr. Holland has called “the hypothesis of insect life as a cause of disease.” I shall not repeat the observations I then made; but I would refer you, for much curious thought and information upon the subject, to Dr. Holland’s very interesting essay. The hypothesis in question squares more readily than any other that I know of, with the ascertained history of the disorder: with its origin, after an unusually wet season, in the low marshy country, and hot atmosphere of Bengal; with its irregular but continuous migrations; with its dying away after a while, and its occasional and partial revivals. But still, remember that we are dealing merely with an *hypothesis*.

Whatever obscurity may overhang the *exciting* causes of the epidemic cholera, we are quite sure that certain circumstances exercised a strong *predisposing* influence upon the human body, to render it more

than usually susceptible of the disease. The predisposing causes, as might well be imagined, were such as tended to debilitate the system: and therefore *poverty*, which implies scanty nourishment, and frequently also the confinement of several persons to a narrow space, and want of fresh air; poverty which includes these and other evils, was found to predispose the body to a ready reception of the malady. But to *intemperance*, more than to any other *single* cause, may the proclivity to become affected by this species of cholera be ascribed; and especially to the intemperate and habitual use of distilled spirits. This fact was peculiarly manifested in the selection, by the disease, of its victims in this country; and it has been remarked almost every where else.

I have all along spoken of the visitation of epidemic cholera in the past tense, because, for the last nine or ten years, we have heard but little of it. Yet we can scarcely venture to hope that the stranger pest has altogether forsaken us, for we have had slight sprinklings of the disease in and near London, every summer, I believe, since 1832; but it has never again been extensively prevalent or epidemic. Certainly it dealt lightly, upon the whole, with our country. It was much more general, and more widely fatal, in France, which it visited subsequently to its arriving here: it was very destructive also in its subsequent course, both westward and toward the south-east.

The epidemic cholera made its attack in two different modes. In one it seized upon the patient suddenly, and without warning. This was comparatively rare. Much more commonly the specific symptoms were preceded, for some little time, even for some days perhaps, by diarrhoea. And this I take to be the most important practical fact that was ascertained during its prevalence among us. When the disease was once fairly formed, medicine had very little power over it; but in the preliminary stage of diarrhoea it was easily manageable. Unfortunately people are inclined (especially those classes of the community among whom the cholera most raged) to regard a loose state of the bowels as salutary, and to make no complaint of it, and to do nothing for it; or, in other cases, they conceive it to proceed from some peccant matter within, which requires to be carried off, and they take purgative medicines to get rid of it. Both of these are serious and often fatal mistakes. Mere neglect of the diarrhoea frequently permitted it to run into well-marked and uncontrollable cholera; and the employment of purgatives hastened or ensured that catastrophe. The proper plan of proceeding, I am convinced, was, to arrest the diarrhoea as soon as possible after its commencement, by astringents, aromatics, and

opiates. You may object perhaps that the cases that were cured in this way were not cases of cholera at all, and never would have been; but simple ordinary diarrhoea. It is impossible to *prove* the contrary, no doubt; but the presumption is strong that the diarrhoea would, in many, and perhaps in most instances, have run on, if not checked, into the more perilous form of the disease. In many places, when, taught by experience, the authorities established *diarrhoea dispensaries*, to which those attacked by looseness of the bowels were warned and invited to apply, that the looseness might forthwith be corrected; in many such places the cholera, which had before been cutting the inhabitants off by scores, and hundreds, began instantly to decline in frequency. I venture to advise you, supposing the disease should reappear, or whenever in the autumn a suspicion arises that this form of cholera is present in the community, not to try, in cases of diarrhoea, to carry off the presumed offending matter, but to quiet the irritation, and stop the flux as soon as you can.

But when the regular symptoms, peculiar to the severe form of cholera, had set in, medicine, I repeat, had very little influence upon it: and accordingly, as might have been expected, a hundred different cures of the disease were announced, most of them all but infallible. Some persons held that timely bleeding would save the patient; others relied confidently upon mustard emetics. Hot air baths were manufactured, and sold to a great extent, to meet the apprehended attack in that manner without delay. Certain practitioners maintained that the disease was to be remedied by introducing into the system a large quantity of neutral salts, which were to liquefy and redden the blood, and to restore the functions of the circulation. But of this practice it was said in a sorry but true jest, that, however it might be with pigs or herrings, *salt*ing a patient in cholera was not always the same thing as *curing* him. In a great number of patients the blood was mechanically diluted by pouring warm water, or salt and water, into their veins. Some physicians put their trust in brandy, some in opium, some in cajeput oil, which rose to I know not what price in the market; some, again, in calomel alone.

Now, I would not willingly mislead or deceive you on this point, by speaking with a confidence which I really have no warrant for, of the success or propriety of any of these expedients. I believe that each in some cases did good, or *seemed* to do so; but I cannot doubt that some of them did sometimes also do harm. I had not more than six severe cases under my own charge: and I congratulated myself that the mortality

among them was not greater than the average mortality. Three died, and three (I will not say were cured, but) recovered. The three that died I was called in to see when the disorder was at its height: in each case it went on with frightful rapidity, in spite of all the means adopted, and proved fatal a few hours afterwards. The three that recovered I saw somewhat earlier, but still not till the specific symptoms were present: one was a girl in the hospital. They all recovered under large and repeated doses of calomel. Yet (as I said before) I do not venture to affirm that the calomel cured them. In the first case which was treated in that way, I merely followed up the plan that had been begun by Dr. Latham, who had visited the patient for me when I was accidentally absent. I found that he had felt better, less sick and less faint, after taking half a drachm of calomel at a dose; and I repeated the same dose many times, for after every dose his pulse rose somewhat, and he appeared to rally. This was the same man whom I mentioned before as having made no urine from the Sunday to the Wednesday: all that time he kept discharging rice-water stools. At last, on the fourth day he passed a *little* water, and his alvine evacuations became rather more consistent, and began to look *green*: and from that time he gradually got well. Afterwards I treated my hospital patient in the same way, and with the same event. Yet I will not pretend to say that these persons might not have done quite as well if they had been left entirely to themselves.

Some of the expedients recommended had certainly a very marked and immediate effect upon the condition of the patients, especially the injection of warm water into the veins. Many instances of this were related at the time. One I myself saw. The patient was a young man, who was nearly moribund apparently. His pulse had nearly, if not quite, disappeared from the wrist; he was very blue, and his visage was ghastly and cadaverous: in one word, he was in an extreme state of collapse. Out of this he was brought in a few minutes by injecting warm water into one of the veins in the arm. The pulse again became distinct and full; and he sat up, and looked once more like one alive, and spoke in a strong voice. But he soon relapsed; and a repetition of the injection again rallied him, but not so thoroughly: and in the end he sunk irretrievably. Dr. Babington told me of a patient whom he saw, speechless, and all but dead, and whose veins were injected. He then recovered so as to sit up, and talk, and even joke, with the by-standers: but this amendment did not last either. Yet even this temporary recovery might be sometimes of great importance: might allow a dying man to execute a will, for example. And some

of the persons thus revived got ultimately well. We had for some time a woman in the Middlesex Hospital acting as nurse, who had been rescued, when at the verge of death in cholera, by the injection of her veins.

It was remarked of those who recovered that some got well rapidly, and at once; while others fell into a state of continued fever, which frequently proved fatal some time after the violent and peculiar symptoms had ceased. Some, after the vomiting, and purging, and cramps, had departed, died comatose; *over-drugged* sometimes, it is to be feared, by opium. The rude discipline to which they were subjected might account for some of the cases of fever. And the system of injecting the veins was certainly attended with much danger. The injection of *air* with the water—inflammation of the vein from the violence done to it—an over-repletion and distension of the vessels by the liquid—*might*, any one of them, and sometimes, I suppose, *did*, occasion the death of the patient. Never, certainly, was the artillery of medicine more vigorously plied—never were her troops, regular and volunteer, more meritoriously active. To many patients, no doubt, this busy interference made all the difference between life and death. But if the balance could be fairly struck, and the exact truth ascertained, I question whether we should find that the aggregate mortality from cholera, in this country, was any way disturbed by our craft. Excepting always the cases of preliminary diarrhoea; just as many, though not, perhaps, the very same individuals, would, probably, have survived had no medication whatever been practised.

I do not know that I have any thing more to say that could be of any use to you, in respect to the epidemic cholera.

## NOTES FROM CLINICAL LECTURES,

*Delivered during the present Session,  
at Univers. Coll. Hospital,*

BY C. J. B. WILLIAMS, M.D., F.R.S.  
Professor of the Practice of Medicine,  
and of Clinical Medicine.

### ON TWENTY-EIGHT CASES OF PHTHISIS— Continued.

*Phtthisis, with purpura, and displacement  
and structural disease of the liver.*

ISABELLA SHAW, *æt.* 70, admitted June 29, on account of an eruption appearing on the legs and arms in numerous purple spots, not removed by pressure, and accompanied with slight tingling, but without papular elevations. This last character distinguished the eruption from lichen lividus. There were besides some ecchymosed patches of large size, and accompanied by some swelling,

from the blood being effused in the cellular texture. These extravasations of blood occurring in several points at once, obviously point to some disease in this fluid. The precise nature of the change is not ascertained, but I have had occasion to remark to you, when commenting on two other cases of purpura which we have had this season, that I have observed purpura to be generally connected with disease or imperfect action of the liver. When we examined the region of the liver in this old woman, we could find no signs of this organ in its usual place. The lower right front of the chest was resonant on percussion, down to the very margins of the ribs, with the deep hollow sound of flaccid emphysema. But in the abdomen, reaching from an inch below the margins of the right ribs to two or three inches below and to the left of the umbilicus, there was a tumor sounding dull on percussion, and offering considerable resistance to the hand. I have no doubt that this was the liver displaced by the emphysematous distension of the lower lobes of the right lung. The thin and flaccid walls of the abdomen enabled us to feel that the surface of this tumor was uneven, with granular prominences; most probably from some degree of cirrhotic deposit in the liver. The bulk of the organ did not seem to be materially changed.

On examining the upper parts of the chest, we found pectoriloquy and cavernous respiration, with unequal dulness of stroke-sound under the clavicles. On further inquiry, it proved that she had an habitual cough, with more or less expectoration, from which she had scarcely been free for several years past. This is another example of that combination which is very usual in old people—chronic tuberculous lesions of the upper lobes, with flaccid emphysema of the lower lobes of the lungs. In a late lecture I explained to you how the latter change must, in many cases, be the result of the former. It is very strange that this very common combination, and its cause, should have been so generally overlooked by pathologists.

The treatment for the purpura was that which you have seen me use successfully in other cases, and it is founded on the fact that the liver is the organ chiefly deranged. Mercurial purgatives and salines, followed by a nitro-muriatic acid mixture, generally suffice to remove the milder forms of purpura. In this case, the age of the patient led me to pass early from the former to the latter remedy. After the purpura had disappeared, the patient was attacked with a very teasing herpetic eruption on the neck and shoulders. This was probably another result of the diseased condition of the blood arising from imperfect action of the excretory organs. You may remember a parallel instance in the formidable case of purpura

which we had at the beginning of the session; the very extensive effusions of blood in the skin and cellular texture were followed by erysipelatous and tubercular inflammations of these parts.

Little was done in the treatment of the chest affection, which was too chronic to need much interference. Henbane was given when the cough was troublesome; and on the occurrence of some increase of chest symptoms, with the removal of the eruption, an antimonial was employed for a few days. This patient left the hospital much improved in strength, and free from all trace of eruption: the cough was much better, but the physical signs were little altered.

*Phthisis, with enlarged spleen and liver.—Bronchitis.*

Samuel Braddon, æt. 36, was admitted Jan. 31, for a great enlargement of the abdomen, which was resisting and dull on percussion from the fifth left rib, down to the iliac region and linea alba. There was dulness also, reaching from the fifth right rib, to nearly as low as the umbilicus; but between these two dull and resisting regions there was a sulcus, sounding tympanitic on percussion, showing the presence of the intestines between two large solid bodies. The form and position of these tumors made it pretty certain that they were caused by enlargements of the spleen and liver. Such enlargements are not unfrequently met with in ague districts as a sequel of intermittent fever; or as an effect of malarious influence, even where regular ague has not occurred. Our patient had not lived in any acknowledged seat of malaria; but he ascribed his complaints to his having, six months ago, worked for a long time as a marble mason in the Temple church, which was very damp and without windows. He then suffered from severe pain in the left side, with a feeling of great chilliness. These symptoms obliged him to give up work, and he was copiously bled and cupped. He became better, and he returned to work in the same place, and again suffered in a similar way, and with swelling of the legs, accompanied by loss of flesh and strength, and his health declined more and more in spite of medical treatment. Since his admission he has also had an habitual cough, consequent on a severe attack of general bronchitis. When he was recovering from this, I found, after repeated examinations of the chest, dulness and rough breath-sound, below the left clavicle, and in the right interscapular region; and these signs have rather increased than diminished. He has also occasional profuse night sweats, and a pulse generally above 90.

For the bronchitis he was treated with antimonials and blistering, which soon relieved him. With the hope of diminishing the hypertrophy of the spleen and liver

small doses of iodide of potassium have been given, with liquor potassæ and sarsaparilla, occasionally varied with a nitro-muriatic mixture when the sweats were profuse. The abdominal swelling has somewhat diminished, but the cough and hectic have become rather more pronounced; and I have no doubt that he will fall a victim to phthisis ere many months are passed.

The combination of phthisis with enlarged liver and spleen has been repeatedly observed; and I need scarcely point out why the latter affections must tend to impair the process of general nutrition, both by drawing away much of its material, and by injuring the structure of organs that are doubtless concerned in preparing or purifying this material.

*Tubercles after Typhus, with congestion of the lungs.*

The case of Daniel Cook, admitted Dec. 14th, has been lately under our consideration as one of typhus complicated with congestion of the lung and liver, from which he recovered, and was discharged cured Jan. 22; but from some dulness of stroke-sound, and prolonged and too loud expiration under the right clavicle, I was led to conclude that some consolidation of a cacoplastic character had been left there. Such results are by no means uncommon after continued fever; induced by the congestion, together with a depraved condition of the blood. I have seen a deposit of miliary tubercles from such a cause entirely confined to the posterior parts of the lungs, these being the most congested, from the posture in which the patient had, for several weeks, lain.

*Pulmonary Tubercles with Epilepsy; Hemoptysis.*

Joseph Scott, æt. forty-one (intemperate, father died of phthisis), was admitted, Sept. 13th, on account of giddiness and slight epileptic symptoms, from which he had lately suffered. He had long been subject to epilepsy. Some weeks before he had been treated in the hospital for profuse hæmoptysis. The cough and chest symptoms were still troublesome, and there was irregular dulness in several parts of the chest, particularly on the right side. He went out, considering himself pretty well, in the beginning of October. His chest symptoms were quiescent, but he still occasionally had epileptic seizures. It is very possible that the cause of the convulsive attacks may have been a tuberculous tumor in the encephalon, probably near the base: epileptic attacks have in other instances been traced to such a cause. Last year we had a case of hemiplegia, in a phthisical subject, which seemed referable to a like lesion. But the circumstances which had lately excited the more frequent operation of this cause in Scott

was, doubtless, the extensive loss of blood which he had lately sustained. It has often been considered inexplicable why tumors and other organic diseases of the encephalon, which are constant and unchangeable, should excite attacks of epilepsy, which are sudden and transitory; but we shall generally find that there is an additional connecting link in the state of the cerebral circulation, which, in the state either of congestion or of determination, brings the constant cause into operation. Now, both congestion and determination of blood in the head are apt to be produced by opposite conditions of the vascular system—that of plethora, and that of sudden inanition; and these are among the circumstances which most commonly excite epileptic attacks.

*Tubercles of the Lungs, with chronic Meningitis.*

The cerebral affection in William Elgood was the most prominent disease; in fact, the tubercles in the lungs, although sufficient to cause irregular dulness on percussion, which had been noted, produced no other symptom than slight cough. The history describes that he had been subject to severe headaches since he was a boy, when he had a fever, with delirium. In the beginning of January, the headaches, which had much increased of late, became so severe as to oblige him to give up work. He was bled, and took medicine, without relief. January 20th his utterance became indistinct: from the 23rd he became somewhat delirious, and remained more or less so afterwards, with intervals of lethargy, in which he tardily and incoherently answered to questions. The pulse on admission (January 28th) was only 78, full and rather sharp: that in the carotid and temporal arteries was remarkably distinct. There were occasional slight twitchings of the left arm. Pupils rather contracted, but answered to light. No paralysis. Slight cough.

The patient was bled and purged, after which he was quieter; but he rapidly lost flesh and strength. The pulse became frequent and feeble; sordes appeared on the teeth and lips, and he lay in a state of partial stupor, with occasional low delirium, until February 2nd, when he died.

*Sectio post-mortem horis xlv.*—Vessels of the meninges generally engorged with blood. Opacity of the arachnoid of both hemispheres, and some recent lymph underneath, chiefly in left parietal region. A considerable quantity of serum at the base of the brain: opacity of the arachnoid, with deposits of yellow lymph in front of the pons varolii. In the fissura Silvii, on the left side, was a deposit of granular lymph: about 3 oz. clear serum in ventricles. Cortical substance dark coloured.

Lungs crepitant throughout, but con-

gested in posterior portions, with some effusion of blood into the tissue of posterior part of left lung. Miliary tubercles in upper lobes of both lungs, and in lower lobe of right lung. Nothing remarkable in other organs.

*Phthisis with various Hysterical or Nervous Symptoms.—Seven Cases.*

We now come to a very numerous class of cases, and one which is particularly deserving of your attention, because these cases are very deceptive, and are rarely understood at a period early enough to give chance of material relief to the more serious disease. You may form some idea of the frequency of their occurrence in the female sex, when you perceive that, out of the eleven phthisical patients in the female ward this winter, seven have been of this disguised or latent description.

In Jane Fearon, æt. 30 (admitted August, discharged relieved October 14th), the chief complaints were emaciation and weakness, with slight evening fever, and occasional night sweats; loss of voice, and superficial tenderness in the left side of the chest and abdomen, without cough, and almost without expectoration. The voice was lost suddenly, and had not been recovered again. She had been subject to hysterical fits. There were also amenorrhœa, and spinal tenderness at the lower cervical and upper dorsal vertebræ: and altogether this bore the aspect of a purely nervous case. But I found distinct dulness below both clavicles, particularly the left, and the expiration was rough and too loud in that situation. This patient was treated with a variety of medicines: the last was tartrate of iron; and galvanic shocks were passed through the larynx October 10th. After two days of this treatment she suddenly recovered her voice.

In Flora Windle, æt. 20 (admitted November 27th, relieved December 15th), the phthisical symptoms were scarcely more pronounced. She was a pale nervous subject, subject to sudden loss of voice, with extreme tenderness of the integuments of the chest and left side. This patient had, however, been subject to a winter cough for five years, and formerly spit blood; and although at present she had scarcely any cough or expectoration, she said she was liable to both when her voice was better. I found partial dulness and tubular respiration under both clavicles, with loud expiration under the left.

She was treated by cupping at first to the painful side; afterwards a stimulating liniment, with Mackintosh covering, to the chest; iodide of potassium and infusion of calumbo internally. The pain in the side was relieved; but the voice was not restored. On December the 11th the larynx

was galvanised; and the next day she suddenly recovered her voice, which she retained on the 15th, when she went out, quite free from cough and expectoration.

Jane Mitcheson, a slight, fresh-coloured young woman, of nervous temperament, was admitted in July for amenorrhœa and severe pain in the left side, with much spinal tenderness, and superficial tenderness of the chest: she also had a slight cough. In my absence she underwent a variety of treatment, including cupping between the shoulders, steel medicines, and the shower-bath. The cupping alone seemed to have benefited her, and that only for a time; and on my return the cough was very troublesome, always excited by percussion of the chest. She had lost flesh, the pulse had become frequent, and night sweats had occasionally occurred. Still the pain and tenderness of the chest and side seemed to be of the exquisite nervous character, and the case might have been considered more hysterical than consumptive. But on examination I found that the right infra-clavicular region was slightly collapsed, and distinctly duller on percussion than the left. Inspiration was indistinct, and expiration too loud under both clavicles. A slight roughness in inspiration, with occasional slight friction sound, was also heard in both supra spinous-fossæ. These signs rather increased on the left side during her further stay in the hospital; and as little relief was given to the symptoms, she was discharged Nov. the 1st.

The case of Louisa Templeman (admitted Nov. 3d, discharged relieved Dec. 30th) has been formerly under our notice. Amongst other complaints there was slight cough and neuralgic tenderness in the chest, chiefly on the left side; and at the apex of this lung we found signs of partial consolidation.

Angelina Williams (æt. 20, fat, and with some colour) had been before she came under my care an inmate of the hospital for some months, with swelling and pain of the knee; and as she had globus and occasional hysterical convulsions, it was considered that her complaints were chiefly nervous, and caused by a suppression of the catamenia. Before I saw her she suffered from severe pain in the left side, with symptoms of gastric dyspepsia, pain and nausea after eating, tenderness of epigastrium, thirst, &c. For a month past she had daily spit more or less blood or bloody fluid without either vomiting or coughing. Generally the blood was only enough to tinge the fluid, which amounted to three or four ounces, and was like saliva, and not frothy; but sometimes the blood was coagulated or fluid, and amounting to an ounce or two. The patient thought that it all came from the stomach, and she denied having the slightest cough: no morbid physical sign had been found in her chest. The pulse generally was about 100.

I first examined the chest on September 14th, and observed less movement and perceptible dulness in the upper part of left side, front, and back : expiration there louder than inspiration : on right side the reverse was the case. From this time I viewed the case to be one of masked phthisis, although it presented many anomalies. The spitting of blood continued in various degrees during her whole stay, until the beginning of Jan. It was not till the end of September that she acknowledged it was attended with any cough ; but after this, the cough, although slight, became more developed, and pellets of mucus, some transparent, some opaque, occasionally appeared in the bloody sputa, which also became less mixed with liquid. The pulse and breathing were always frequent during the visit ; the former ranging from 104 to 120, but when taken quietly in the morning it was found as low as 60. The pain of the left side was never removed ; but sometimes it extended to the chest and right side, and was generally attended with superficial tenderness. In spite of the symptoms, many of which were really distressing, in spite of the constant spitting of blood, in spite of the depletion which was frequently used for the temporary relief which it gave to the symptoms, in spite of the moderate and sometimes low diet, necessary from the occasional gastritic symptoms, this patient never lost flesh, but throughout retained her *embonpoint*, naturally considerable. To look at this patient she appeared anything but consumptive ; yet the physical signs became distinct and unequivocal, first on the left side, and afterwards on the right. In the reports, which were very accurately kept by Messrs. Canney, Leonard, Hare, and Heaton, you will see it stated, from time to time, that various morbid sounds were heard in the upper parts of the chest ; such as length, loudness, roughness, of the expiratory sound ; slight strepitus, between a creaking and crepitation, with expiration ; submucous and subcrepitant rhonchi. The expectoration became less sanguinolent about the end of November ; but it occasionally presented a mixture of muco-purulent matter.

I must refer you to the reports for the treatment pursued in this case. It was much varied, because little effect seemed to ensue from the use of any remedies, except local blood-letting, which always gave temporary relief to the pain in the side and chest. Hot pediluvia, and leeches to the sacrum and thighs, produced no benefit, and counter-irritation gave no ease to the pain, although employed in many forms of rubefacient liniments, blisters kept open, croton-oil, and tartar emetic, pustulating applications, and a large seton to the left side. The quantity of blood in the expectoration, which had been unaffected by acetate of lead, turpentine, mineral acids, alum, sul-

phate of zinc, muriated tincture of iron, and other reputed styptics, became gradually diminished during the use of a turpentine and acetic acid liniment, covered with a piece of India-rubber cloth ; but it never entirely ceased, and I hesitate to ascribe its diminution to this application, and the cough became more troublesome afterwards. The employment of internal remedies was limited by the irritable state of the stomach. Salines, with hydrocyanic acid, and various narcotics, were useful for a short time ; but nothing tonic was borne. The bowels were in an unmanageable state, and required mild doses of hydrarg. c. cretâ, followed by castor oil, or similar aperient, to keep them in action. Towards the end of December a slight diarrhoea occurred, with tenderness of the abdomen. The remedies just mentioned were then used, with Dover's powder ; and there followed an amendment sufficient to enable us to discharge the patient relieved on the 4th of January. The report then is—"Much less pain in the chest, less cough and expectoration of blood, and pulse less frequent ; but none of these symptoms are removed. The catamenia were not restored."

The case of Polixine Cœuret, æt. 17, so closely resembles the last case, that I shall dismiss it in a few words. She was admitted October the 26th for an impetiginous eruption on the face and legs, with gastritic dyspepsia ; these were soon removed : but it was found accidentally that she was daily spitting blood, mixed with masses of opaque muco-purulent matter, yet with very little cough. She had not menstruated for five months ; and stated that she had for that time had a very slight cough, with shortness of breath, and had been getting somewhat thinner, although she was now a stout, well-formed girl, with a quiet, good pulse, and very little appearance of ill health. Soon after her admission, the pelvis was daily galvanised, with the hope of restoring the catamenia ; after this she walked in her sleep, and twice had fits of insensibility, with slight convulsions. The pain in the chest and side was accompanied by tenderness of the surface and of the dorsal vertebræ.

Equivocal as were these general symptoms, the physical signs left no doubt of the existence of considerable disease in the lungs. Dull stroke-sound, tubular breath-sound, with loud expiration, were observed below the right clavicle soon after her admission. Subsequently mucous rhonchus and cavernous breath and voice sounds in the same situation distinctly followed the daily expectoration of clots of opaque, foetid, yellow matter with blood. Dulness and subcrepitation were observed more recently below the left clavicle ; whilst the stroke-sound improved under the right, and cavernous phenomena became less distinct. Many

general symptoms appeared some time after her admission, more in conformity with the diagnosis formed; such as night sweats, more constant cough, breath short, and pulse frequent: yet she never appeared to lose flesh. The expectoration of blood and matter was very much diminished towards the end of January after a variety of treatment, the last of which was with occasional cupping to the chest, and a mixture with muriated tincture of iron and nitre. The iron was discontinued soon after, on account of severe headache, and infusion of calumbo given. She was discharged February the 21st; the symptoms being all much alleviated, but, like in the last case, not removed. The pulse had again fallen to 80. The catamenia had not reappeared.

The latter state of Elizabeth Freethy, whom I have before noticed in this lecture, was becoming much like that of the two last cases; and I have met with eight or ten cases in private practice in which phthisis has come on in a similar way in females. The remarkable features in these cases are imperfect or suppressed menstruation; the daily expectoration of more or less blood for a considerable length of time; the absence of considerable emaciation; the absence or trivial character of the cough at first, and sometimes its convulsive character at a later period, and throughout the predominance of various symptoms called hysterical or nervous, such as hysterical fits or sensations, neuralgic pains, nervous dyspnoea, palpitation, dysuria, &c.

I must again warn you against the common mistake of considering such cases as mere hysteria, because they present many nervous symptoms. Phthisis attacks hysterical subjects as well as others; and in them the symptoms of phthisis are conjoined, at first at least, with those of hysteria. Nay, I believe that the irregularity of functions, the state of general ill health, that in nervous females constitutes aggravated forms of hysteria, is a condition peculiarly predisposing to phthisis. No sooner are tubercles deposited than they become the local cause of various nervous and vascular affections which accompany hysteria, neuralgic pains, sympathetic irritation, convulsive cough, asthma or dyspnoea, sanguineous congestion, or actual hæmorrhage, either occasionally vicarious of, or constantly superseding, the natural uterine discharge.

Another cause of deception is, that these cases are usually slow in progress, which confirms the practitioner in the opinion that they are merely "hysterical." I formerly thought much less than I do now of a female expectorating blood. If it be at the menstrual period we are often told that there is no harm in it. I am not prepared to say that females may not expectorate blood with-

out disease of the lungs; but I must now say that of late years I have met with none who have repeatedly expectorated blood, even at the catamenial period, whose lungs were sound. Several private patients, who have been for years under my notice, whom I used to refer to the former category, I have been obliged, by later observation of the progress of the disease, to include under the last.

The truth seems to be, that in an hysterical or nervous subject, effects and symptoms are produced by a smaller amount of tubercle, or of any organic disease, than in one that is not nervous, yet the effects and symptoms that are so induced are less those commonly resulting from the organic disease than those of hysteria; or at least some combination of the two, in which the nervous phenomena eclipse the rest. Hence the more serious disease, although advancing, is masked, whilst the acknowledged nervous disorder gains full attention.

To avoid these errors, study closely the physical signs. Percussion, used according to the principles and varied methods which I have explained to you, will generally give earlier indications of tubercles than auscultation will. The duller or more raised stroke sound, under a clavicle, in the top of an axilla, or on the spine of a scapula, is often the earliest sign. With it, or soon after it, there may occur defective, tubular, or rough inspiratory sound; distinct, prolonged, rough, vibrating, or crackling expiration; with submucous, subcrepitant, or sibilant rhonchi; increased vocal fremitus; and, in cases of more extensive deposit, irregular or imperfect movement of that part of the chest during the respiratory actions. In practising percussion in these nervous subjects, we often find that the stroke excites cough, particularly on the most diseased side. It is possible that such an effect might ensue from mere neuralgic sensibility; but I do not remember to have met with an instance of chronic affection in which it was not accompanied by signs of partial consolidation of the lung.

## VACCINATION.

*To the Editor of the Medical Gazette.*

SIR,

THE remarks in your leader for the week before last, upon the scantiness of the Annual Report of the National Vaccine Establishment, must awaken in the minds of many of your readers a reflection or two upon the "literary parsimony" on this same subject, which has latterly been evinced by the profession at large. If we may judge, at least, by the weekly medical press,

there has not for many years been a time when vaccination has occupied so little of the attention of the Faculty, as during the last year and a half that we have been favoured with an Act of Parliament expressly devoted to the matter: and yet, as far as my own limited knowledge goes, the operation has been more frequently performed in that short time than in double the time at any period before the Act. Can it be that, while there is more practice of vaccination, there is less observation of it worth recording?

One great cause of regret at the infrequency of papers on the subject is, that the few which do appear must be, statistically speaking, comparatively worthless, from the limited extent of individual experience, and the absence of any large accumulation of cases from other quarters, with which, as a standard, each fresh accession may be compared.

This inconvenience may, perhaps, be well illustrated by reference to a paper by Mr. Paterson, of Aberdeen, at page 546 of your last volume. This gentleman, apparently from an observation of only a hundred cases, arrives at certain most weighty conclusions as to the cause of failure in the operation of vaccinating, and in the prophylactic power of cowpock. I lately hazarded some inferences from my first three hundred cases under the Vaccination Act, which inferences were nearly all at variance with those of your correspondent. "Failures," he says, "arise (most, if not all,) either from the constitution of the child from whom the virus is taken, or from some mismanagement on the part of the operator." It is not clear, from the context, whether Mr. Paterson here means failure to produce cowpock, or failure of cowpock to prevent variola. If the former, my experience is opposed to the proposition; if the latter, namely, that cowpock derived from an unhealthy patient is of inferior prophylactic power, I fear the united experience of that gentleman and myself, however extensive, would hardly be large enough to do much towards settling the question. One point I feel confident is of the greatest importance—never to give the cowpock to a child that is out of health. I have seen undoubted and fatal proof of the propriety of this rule.

The "mismanagement on the part of the operator," to which so many failures

are attributed by Mr. Paterson, is indicated, in an earlier paragraph, to be the "operating before the pock is perfectly matured." Now, in the 300 cases before alluded to, I found the success of the operation to increase regularly in proportion to the earliness of the day on which the inserted lymph had been taken. Thus, ten-day lymph succeeded in only half the cases in which it was used; lymph of the eighth day had four successes to one failure; of the sixth day, eight successes; and lymph of the fifth day, as many as twelve successes to one failure. "Lymph," it is said, "is not unfrequently taken from a mere pimple." Waiving the objection that this can hardly occur if a pimple is not a vesicle, but a solid eruption, I believe I adopt the opinion of several high "written authorities" in saying that the sooner lymph can be got, the surer are we of making it produce the disease in a second patient.

As to the early age of the patient vaccinated being a cause of failure (to produce the disease), I perfectly agree with Mr. Paterson. Of 63 children vaccinated under two months, 37 took cowpock, and 26 failed. Of 67, from two to six months, 46 succeeded, and 21 failed; while, of 64 cases, at from one year to two years old, 61 took, and the failures were only 3!

Where small-pox prevails, or where there is anxiety on the part of the parents, vaccination, of course, cannot be performed too early; and the operator must guard himself as he can against discredit in case of failure. But where no such causes of haste exist, the period named by Mr. Paterson, that is from the fourth to the sixth month, would seem to be in general the most eligible.

As to the retardation of the course of the disease, this, I think, happens less frequently than a delay of the time at which the operation begins to take effect. In one case, I well remember nearly three weeks elapsing before a vaccination showed any effect; and thenceforward the disease went on at the usual pace, completing its areola about the ninth day from the time when the first sign of success had appeared.

My object, however, in these remarks, being rather to show the necessity of further information on the minuter details of the subject—information which the recent statute, one would think, ought to render abundant

—than to offer any positive views of my own in the same breath with my acknowledgment of the insufficiency of my data, I shall only express a hope that the powers given by the legislature may have the effect, not only of extending the practice, but of improving the science, of vaccination; and beg leave to subscribe myself,

Your most obedient servant,  
F. A. B. BONNEY.

Brentford, April 5th, 1842.

---

AN ENQUIRY  
INTO THE RESULTS OF  
PUNCTURE OF THE HEAD, IN  
CASES OF CHRONIC INTERNAL  
HYDROCEPHALUS,

BY CHARLES WEST, M.D.

Physician to the Finsbury Dispensary.

(For the London Medical Gazette.)

---

SOME months since a case of chronic hydrocephalus came under the writer's observation, in the management of which a question arose as to the propriety of performing paracentesis capitis. The operation was performed, but was not followed by any amelioration in the condition of the child, which died seventeen days afterwards.

While engaged in watching this patient, the writer referred to various sources, in order to ascertain what prospect of recovery is afforded by the operation. He met with reports of many isolated cases, and with opinions very positively expressed both in favour of paracentesis, as well as against its performance; but no work presented the results of actual experience. The following paper is intended to supply, in some slight degree, this deficiency, and to spare others the irksome task of hunting through volumes of journals, in which these cases are for the most recorded.

The history of the operation does not require more than a passing notice. In Hecker's dissertation\* will be found full details of all that has been said concerning it by the writers of antiquity. Hippocrates was well acquainted with it, and it appears to have been occasionally practised, by surgeons in the middle ages, since, though it is now condemned by some as useless and dangerous, or spoken of as having fallen into disuse. Until the middle of

the last century it was customary to allow as much fluid as could be evacuated to flow through the puncture. Le Cat, however, modified the operation by permitting the escape of only a small quantity of fluid at one time; and for the more convenient attainment of this object, he devised a peculiar trocar, of which a drawing and description are given in Vol. 47 of the Philosophical Transactions. Since then the operation has been frequently resorted to, although the weight of authority was against its performance, until the recent announcement of Dr. Conquest that he had had recourse to it in 19 cases, in 10 of which he had obtained favourable results.

The writer has found mention of 63 cases of chronic hydrocephalus in which the cranium was punctured.\* In two of these cases, however, the puncture was accidental,† while in five instances the results were not such as would justify classing the cases either as fortunate or unsuccessful.‡ Fifty-six cases then remain, in 40 of which the patients died, while in 16 they are alleged to have recovered; or, in other words, the proportion of recoveries to deaths was as 1 : 2.5, and as 1 : 3.5 of the total cases. These results, though considerably less favourable than those obtained by Dr. Conquest, still appear at first sight to afford ample justification of the operation: but the particulars contained in the following table will, perhaps, in some degree modify such an opinion.

---

\* Two cases in which the fluid was accumulated between the scalp and cranium, constituting external hydrocephalus, are purposely omitted. They are described by G. C. Fenoglio, in *Omodei, Annali Universali*, vol. xxviii. p. 370; and by K. Textor, in *Meissner's Forschungen*: vol. iii. p. 342.

† These are the cases of Greatwood, (*Lancet*, May 23, 1839, p. 238), in which the puncture was made by a nail; and Höfling, *Casper's Wochenschrift*, Oct. 14, 1837, in which a hydrocephalic head was burst by a kick from a cow. The patient in both instances recovered.

‡ Hotbroke, *London Medical Repository*, vol. xxiv. p. 246. Head punctured thrice, with slight amendment: final result not stated.

Dr. Vose, *Med. Chir. Transactions*, vol. ix. p. 354. Improvement from the operation, but disease returned, and destroyed the patient.

Dr. Conquest, *Lancet*, March 17, 1838, p. 800. Case of W. Hattoney: died of pertussis some months afterwards: placed by Dr. C. among his unsuccessful cases.

Dr. C. A. Lee, quoted in *Stewart on Diseases of Children*, p. 353. Punctured twice with benefit. Child died of cholera twenty days after second operation.

Dr. Kilgour, *Edin. Med. and Surg. Journal*, vol. lili. p. 363. Head punctured four times, operation then discontinued; no benefit seeming to accrue from it.

\* *Antiquitates Hydrocephali*, &c. Auctor. J. Fr. C. Hecker, 8, Berol.

No.	Sex.	Age.	Duration of Disease.	Symptoms before Puncture.	Size of the Head.	Number and Date of Punctures.	Quantity of Fluid in lbs. and ounces.
1	—	b'tween 11 & 12 years	—	Came on in consequence of a fall; head enlarged to a third beyond natural size, and parietal bones opened so as to allow fluctuation to be felt. These symptoms came on three months after the fall.	A third larger than natural.	One	lbvj. of water drained away in 20 days.
2	F.	4 m. 11 days	began in 6th week	Began with fits and enlargement of head. Bowels torpid; strabismus; child had an idiotic look.	Apparently double.	Eighteen Dec. 10. 17. 25. 28. 31. Jan. 5. 9. 14. 19. 23. 28. Feb. 4. 8. 18. 25. Mar. 3. 6. 10.	oz. $\frac{1}{2}$ + 5 + 4 + $5\frac{1}{2}$ + 4 + 4 + 7 + $7\frac{1}{2}$ + 7 + $2\frac{3}{4}$ + 10 + $3\frac{1}{2}$ + 0 + 0 + 5 + 3 + 4 + 4 = $76\frac{1}{4}$ .
3	F.	12 wks.	began a few days after birth	General health good, but bowels irregular; strabismus, and rolling of the eyes.	23 inches incircumference.	Four August. 25. Sept. 4. 15. Oct. 5.	oz. 3 + $5\frac{1}{2}$ + 1 + $9\frac{1}{2}$ = 19.
4	M.	4 mths.	head large at birth	Child healthy, cheerful, not emaciated. The fluid was supposed to be external to the ventricles.	$18\frac{1}{2}$ inches in circumference.	Eleven Jan. 8. 15. 23. Feb. 19. Mar. 15. 19. Apr. 19. 27. May 5. 17. June 23.	oz. $1\frac{1}{2}$ + 2 + 2 + $2\frac{1}{4}$ + $1\frac{1}{2}$ + $2\frac{1}{4}$ + $1\frac{1}{2}$ + $1\frac{1}{2}$ + $2\frac{1}{4}$ + $2\frac{1}{2}$ + 2 = $21\frac{1}{4}$
5	—	14 m.	—	—	—	Nine within 4 months.	Ojas. by first puncture, less by subsequent ones.
6	—	10 m.	excited from birth	Child very ill; pupils dilated. States that inflammation of the brain and its membranes existed, but does not mention a single symptom.	—	One	oz. 24.
7	F.	20 m.	began in 14th mth	Head had been gradually enlarging for half a year.	—	One	oz. 2, but a large quantity, supposed to be Oij. drained away.
8	M.	5 mths.	congenital	Hiccough and vomiting; eyes heavy, somewhat convulsed.	Head of enormous size from birth.	Two beginning of Aug. Sept. 3.	oz. 12 + 12 = 24.
9	F.	—	—	—	—	Five	oz. 55.
10	F.	—	—	—	—	Three	oz. 26.
11	F.	—	—	—	—	One	oz. 13.
12	F.	—	—	—	—	One	oz. 9.

Subsequent Progress.	Date of Report.	Authority.
"Patient was saved."	—	Monro on Hydrocephalus, p. 146, quotes the case from Pr. Rossi.
The fluid removed was clear first, but, on the 8th and 9th punctures, was of a darker colour and thicker consistence, but regained its transparency at subsequent operations. The immediate effects of the puncture were never serious. Slight febrile symptoms, and occasional vomiting, and fretfulness, occurred at different periods, but fits only once, just before the sixth operation. The ossification of the head proceeded so that the situation of the first puncture became ossified.	Ninety days after first puncture; day of last puncture. Case then going on favourably.	Mr. Lizars, Ed. Med. and Surg. Journal, vol. xvii. p. 243.
The fluid was serous, on the second time was turbid and mixed with flakes of lymph. Slight fever after first, not after others. Ossification advanced; head diminished; child went on well; obscure fluctuation remained three weeks after last puncture. Calomel was then given, so as to affect the mouth.	Four months after last puncture, then stout, healthy, and very large of her age. Head ossified, except anterior fontanelle, and four inches less in circumference.	Mr. Russell, Ed. Med. and Surg. Journal, vol. xxxviii. p. 43.
After each operation there was great faintness, pallor, and failing of the heart's action during several hours. Great restlessness followed for a night or two after each operation.	Seventeen months after last puncture, child was healthy, and head measured 18½ inches in circumference.	Graefe. Graefe and Walther's Journal, Bd. xv. S. 348.
Great improvement followed the first puncture; the others left the child in a very satisfactory state.	Died of pneumonia more than a year afterwards.	Dr. Fourcade, Lancette Française, vol. iv. No. 47, p. 188, reports from recollection case operated on by Dr. Bédor.
Iodide of potassium ointment employed; calomel and mild aperients given. "Though the little sufferer was for some time in a precarious state, he did recover, and is now a very fine boy, never having had the slightest return of the complaint."	—	Mr. Marsh, MED. GAZ. vol. xvii. p. 985.
One convulsion followed the puncture, and afterwards other symptoms of meningeal irritation.	Two and a half years afterwards health and intellect good.	
Continued weakly during the day of puncture, but more lively than before, and for some time after the intensity of all the former symptoms diminished. A month after it was found necessary to repeat the puncture.	Nearly eight years after, head then too large, but not larger than before the operation. Health good.	Dr. Conquest, Lancet, March 17, 1838; and MED. GAZ. vol. xxi. p. 967.
—	Five years after, head 22 inches round; ossification complete, except posterior fontanelle, and two openings in coronal suture. Health good, remarkably shrewd.

—		

Chronic hydrocephalus is a disease usually slow in its progress and intermittent in its advances, occasionally pausing for months, or even years, and then increasing without any evident cause. Before any case, then, can be admitted to have been cured by the operation, it must be shown that a considerable time had elapsed since its performance; and that during this period the health of the patient was perfectly good. Nos. 4, 7, 8, and 9, are the only instances in which both these conditions are fulfilled. In No. 5, the former condition is complied with, but the evidence of the patient's health is very unsatisfactory; the case being reported some years after the death of Dr. Bédor, while nothing can be more vague than the statement that the child was left *dans un état très satisfaisant*. The history of Mr. Russell's patient is com-

plete; but with the evidence afforded in Dr. Vose's case, in which the disease returned and proved fatal after apparent recovery, we should be slow to admit four months as a period sufficiently long to test the permanence of the cure. In the child operated on by Mr. Lizars, decided improvement seems to have followed the puncture; but his report of the case was forwarded on the very day on which he performed paracentesis for the eighteenth time, and of the subsequent history of the patient nothing is recorded. But, defective as the cases are in the above-mentioned respects, they are not less so in the absence of information as to the condition of the child before the puncture was resorted to. Cases 2, 3, and 4, are the only ones in which this condition is at all satisfactorily fulfilled. Very imperfect notices exist of Nos. 1, 6, 7, and 8; leav-

TABULAR VIEW OF CASES OF INTERNAL HYDROCEPHALUS IN

No.	Sex.	Age.	Duration of Disease.	Symptoms before Puncture.	Size of the Head.	No. of Punctures.	Quantity of Fluid.	Immediate Effect.
1	M.	9 m.	Began at 3d month.	Sucked well, but was emaciated.	At 8th month larger than head of a man.	One	1lb. Fluid continued to drain away afterwards.	—
2	M.	3 m.	Began in 7th week.	Well nourished, but fretful.	Sutures separated.	Three	5 + 5 + 5 = 15	—
3	—	3 m.	—	—	Very large.	One	—	Bore operation well.
4	—	2 m.	Congenital.	Healthy and strong: head had much increased in size; eyes very prominent.	—	Five	10 + 12 + 14 + 12 + 32 = 80	—
5	M.	2 y.	Congenital.	Well.	25 inches round at 6th month	One	—	—
6	F.	5 m.	Noticed at 5th month	Indisposed for three weeks with crying and screaming. Pupils immoveable.	Very large, fluctuating.	Six	9½ + 9½ + 6 + ½ + 2½ + 1½ = 29½	Sickness and vomiting after 2d; 4th puncture made in the fontanelle; 4½ oz. of blood escaped, and child seemed like to die.

ing 9 out of 16 cases in which this point is passed over in silence.

It would have been interesting to have been made acquainted with the circumstances to which the brilliant success of the operation in Dr. Conquest's hands is attributable. But, unfortunately, no data are given in 15 out of 19 cases, beyond the mere statement of the number of punctures, and the quantity of fluid removed. The age of the patient, the duration of the disease, the symptoms attending it, the size of the head, and the condition of the intellectual faculties before and after the operation, are not noticed. We are left in perfect ignorance as to the time which elapsed before each patient was reported as cured ; and yet, on grounds so slender, an impression has got abroad in this country and elsewhere

that paracentesis capitis is a means to which recourse may be had in cases of chronic hydrocephalus, with a well-founded expectation of success.

From numbers so small, and furnished with such imperfect details, it would be impossible to attempt any numerical exposition of the chances of recovery afforded by the operation. An analysis of the first table has shown how few are the instances in which permanent cure has been proved to have resulted from its performance. The second table not merely exhibits the great preponderance of failures over successful cases, but likewise shows that in very many instances an aggravation of the symptoms followed the operation, and that life was apparently much shortened by it.

WHICH PARACENTESIS WAS UNSUCCESSFULLY PERFORMED.

Subsequent Progress.	Date of Death.	Condition of the Brain after Death.	Authorities.
Child sank.	36 hours after the puncture.	—	Fabricius Hil-danus, Ob-serv. Chirurg. cent. iii. obs. 17.
Well for 2 days, then taken ill : died on evening of 4th day.	84 hours after 1st, 36 after last puncture.	Excessive dilatation of ventri-cles ; atrophy of pineal gland ; very little trace of choroid plexuses.	Le Cat, Philo-soph. Trans. v. xlvii. p. 257.
—	Day after the puncture.	Fluid between cranium and dura mater.	La Motte, Traité com-plet de Chi-rurgie, tome i. obs. 115.
After 3d puncture, head re-duced to natural size ; after 1st week, head swelled again. Exhaustion came on 3 weeks after 5th puncture ; death in 10 days.	3 months 9 days after 1st, 31 days after last puncture.	Cavity of brain full of enormous quantity of clear water ; scarcely any brain found, but only me-dulla oblongata, and a small quantity of brain behind the orbits.	Dr. Remmett, Edin. Med. Comment. vol. vi. part 4.
—	16 hours after puncture.	Two pounds of clear fluid con-tained in brain, in cysts, with vascular coats ; cerebellum around fourth ventricle hard ; crura cerebri ulcerated.	Dr. A. Monro, Morbid Ana-tomy of the Brain, vol. i. p. 11.
More lively ; convulsions ; and hemiplegia affecting right side, on 3d day after 1st punc-ture ; ceasing in course of one day. Diarrhœa for some days. Coma before 2d and 3d punctures ; relieved by the operation. Seemed better on day of 6th puncture ; fits on following day ; tranquil death soon after.	37 days after 1st, 1 day after last puncture.	Two pounds of sero-sanguineous fluid in ventricles ; walls of ven-tricles very thin ; brain soft ; coagulum size of a hazel-nut in posterior corner of left lateral ventricle.	Mr. R. Brown, Med. and Phys. Journal, vol. li. p. 102.

No	Sex.	Age.	Duration of Disease.	Symptoms before Puncture.	Size of the Head.	No. of Punctures.	Quantity of Fluid.	Immediate Effect.
7	M.	9m 20d	Con- genital.	Good, and continued so, notwithstanding fruitless employment of medicines; head hot, appetite craving.	23 inches round above tips of ears.	Ten	$4\frac{1}{2} + \frac{1}{4} + 5 + 3 + 3\frac{1}{2} + 3 + 3\frac{1}{2} + 3\frac{1}{2} + 4 + 2 = 40$	No striking effect.
8	M.	9 m.	Con- genital.	Child had a spina bifida, but health good.	27 inches round.	Three	$10 + 16 + 14 = 40$	—
9	F.	4 m.	Con- genital.	General health good; head had progressively enlarged.	24 inches round.	Eight	$12 + 12 + 12 + 9 + 12 + 3 + 9 + 12 = 81$	Very slight except after 5th puncture, when faintness was produced.
10	—	6 m.	Six or seven weeks after birth	Always unquiet, but tolerable health to 5th week; became gradually emaciated; bowels irregular; constant crying, no sleep.	23 inches round.	One, but wound opened twice a day for several days.	116 in course of 8 days.	—
11	M.	7 m.	Began about a month after birth	Fever; screaming; squinting at 3d week; in 10 days enlargement of head, which increased; other symptoms abated.	$21\frac{1}{2}$ inches round.	One	6	Vomiting soon after.
12	M.	8 m.	Began in 3d month.	Sickly from birth; convulsions at 2 months; emaciation; constant crying; strabismus.	$21\frac{1}{2}$ inches round.	Five	$14\frac{1}{2} + 3\frac{1}{2} + 7 + 7 + 16 = 47\frac{1}{2}$	Uneasy during 1st, sensible of pain afterwards; uneasy, and occasionally convulsed after 5th.
13	M.	11 w.	Began in 6th week.	Always fretful, throve till 6th week, then wasted; head swelled. No squinting.	Fluctuation in head distinct.	Six	6 by first, afterwards $+ 36 = 42$	No inconvenience; sensible improvement.
14	M.	5 m.	Began at 2 months.	Good for two months, but head always inclined to side; then swelling of head, fits of crying, cough, and emaciation. No vomiting or convulsions.	$20\frac{1}{2}$ inches in circumference.	One	11	None; head much collapsed; vomited same evening.
15	—	5 w.	—	—	Supposed to contain 2 to 3 pints.	Five	$4 + 3 + 4 + 4 + 4 = 19$	—
16	—	$6\frac{1}{2}$ m.	Began in 4th month	Well nourished: general symptoms very slight.	—	One	37	Brain protruded through 1st puncture (with a lancet), which was therefore repeated.

Subsequent Progress.	Date of Death.	Condition of the Brain after Death.	Authorities.
Slight improvement followed each puncture. Continued well, except erysipelas of face, till day of last puncture; then, convulsions returning frequently, child wasting till death.	84 days after 1st, 11 after last puncture.	Dura mater thickened; pia mater inflamed; cerebral substance very thin, lined by false membrane; no trace of corpus striatum, callosum, &c.; bag of cerebrum divided into cells by membranous bands, contained 35 oz. of fluid; cerebellum firm.	Mr. Money, Med. and Phys. Journal, vol. lii. p. 462.
—	30 days after 1st puncture, 9 after last.	—	Mr. Gray, Med. and Phys. Jo., vol. liv. p. 204.
Health good for a few days: considerable exhaustion after 2d puncture. On 5th puncture, 6 weeks after 1st, situation of original puncture ossified. Two convulsions before 7th puncture, again after 8th.	110 days after 1st, 8 after last puncture.	Fluid between dura and pia mater; the former thickened, but with no signs of acute inflammation; brain nearly all absorbed, not larger than a hen's egg, soft, and parts not distinguishable.	Dr. Glover, Philadelphia Jour. of Med. and Phys. Sciences, vol. ii. p. 159.
Seemed going on well, though fluid re-collected; head greatly diminished in size; sutures, which had been 3 inches across, came into apposition. On 9th day, convulsions, coma, death.	9th day from making the puncture.	Membranes gangrenous for several inches round puncture, contained four pounds of turbid, foetid fluid; whole upper part of brain disappeared; some at base, like pons varolii.	Dr. Witmore, American Med. Recorder, July 1821.
First night restless; next night better; screaming 58 hours after, followed by fits; and death, in fit, 14 hours after.	72 hours after puncture.	No trace of inflammation; brain very soft; two transparent sacs in left ventricle, one in right communicating with third and fourth: they were smooth and tough, attached to brain at under, unconnected at upper surface; nates and testes formed a tumor, containing 1 drachm of pus; lower parts of brain healthy.	Mr. Hood, Ed. Med. Surg. Journal, vol. xvii. p. 510, Oct. 1821.
Slight convulsions on night after 1st puncture; improvement, less strabismus, increased ossification; cried much after 4th convulsions, and death 3 days after 5th.	51 days after 1st puncture, 3 after last.	No sign of inflammation; fluid in ventricles; brain greatly expanded; cerebellum healthy.	Dr. Freckelton Ed. Med. Sur. Journal, vol. xvii. p. 240.
Relief after each puncture; a fortnight after last, water ceased to accumulate. No ossification of skull took place.	11 weeks after 1st puncture, 3 after last.	No sign of recent inflammation; 2½ lbs. of fluid in sac of arachnoid; atrophy of cerebrum which was not larger than a bean.	Mr. J. Sym, Ed. Med. Sur. Journal, vol. xxiv. p. 295.
Went on well till 3d day, head being 2½ inches smaller. On 3d day, great restlessness, vomiting, rigidity of one arm, convulsions: death on 4th day.	87 hours after the puncture.	No inflammation of brain or its membranes; ventricles contained yellowish white fluid, like seropurulent fluid and water, with albuminous flakes; some softening of ventricles.	Dr. J. Alison, Ed. Med. Sur. Journal, vol. xliii. p. 359.
—	16 weeks after 1st, 5 weeks after last operation.	—	Mr. Callaway, as reported by Oppenheim, Rust's Mag., v. xxiv. p. 77.
Pretty well, but somewhat excited 1st day; head filled again between 3d and 6th day; on 7th, a gush of fluid from situation of 1st puncture, followed by convulsions and involuntary discharge of urine and feces.	9th day after the puncture.	—	Dr. Roechling, Hufeland's Journal, Aug. 1826, p. 114.

No	Sex.	Age.	Duration of Disease.	Symptoms before Puncture.	Size of the Head.	No. of Punctures.	Quantity of Fluid.	Immediate Effect.
17	F.	16 m.	Began at end of 3d month.	Began with convulsions; health then good until dentition began, then lost motion of left arm and leg; had fits with each tooth, and occasional strabismus.	26 inches round.	One	2½, and more drained from wound.	Considerable collapse.
18	F.	16 m.	Began in 4th month	Health bad; pupils dilated; insensible to light; coma for several months; occasional convulsions.	—	One	20	Cold, faint, lips livid, requiring strong stimulants.
19	F.	6m. 3w	Began at 5th month	Great strabismus.	18 inches in circumference.	Four	9 + 2 + 3 + 2½ = 16½	No suffering.
20	—	15 w.	—	—	—	One	10	—
21	—	9 m.	—	Great emaciation.	30 inches in circumference.	One	10	—
22	—	2 m.	Con-genital.	Health tolerably good — child intelligent.	23 inches in circumference.	Two	28	Improved appearance.
23	M.	4 m.	Began at 1 month.	Good, except frequent convulsions.	21 inches in circumference.	Seven	1½ + 2 + 6 + 11 + 15 + 12½ + 14 = 63	None.
24	—	3 m.	Began at 1 month.	Health good, but bowels costive; had spasms when a week old, ceased after 3 weeks, when head suddenly enlarged.	—	Four	14 + 17 + 14 + 13½ = 58½	Slight hæmorrhage from a vessel at 3d puncture.
25	M.	7m 12d	Began at 2d month.	Small-pox at 5th week; enlargement of head from 2d month; at 5th month blind; oscillation of eyes; starting and screaming, afterwards fits.	22½ inches round at 5th month	Ten	4 + 5 + 6 + 7 + 12 + 16 + 12 + 28 + 42 + 20 = 153	After 3 of the punctures, faint and pale, and once vomited. Nothing after any of the others.

Subsequent Progress.	Date of Death.	Condition of the Brain after Death.	Authorities.
A little improved 1st night, pretty well till 3d day; then violent convulsions and death.	4th day after the puncture.	Brain bloodless; 2 lbs. of fluid in ventricles; great thinning of their walls, of right especially, which formed a mere membranous bag, and was in parts of consistence of cream; parts at floor of left ventricle barely recognizable; at floor of right undistinguishable; cerebellum and base of brain healthy.	Dr. S. Hall, MED. GAZ. vol. vi. p. 334.
Slight fever for a few days, then seemed better. In 10 days water began to accumulate. In 1 month and 3 days symptoms of nervous debility, in 3 days more painless death.	5 weeks after the puncture.	No trace of inflammation; great accumulation of fluid in the ventricles.	Mr. Marsden, Lancet, Feb. 12, 1831, p. 648.
Vomiting on 2d and 3d day, fever on 4th, coma on 5th, convulsions on 6th.	6 days after puncture.	One pound of fluid in cranium; puncture had not penetrated the brain; dura mater adherent to skull; brain soft and very vascular; great distension of lateral ventricles with fluid; no inflammation about puncture.	Oppenheim, Rust's Mag. v. xxiv. p. 89.
—	—	All the ventricles formed but one large cavity, covered by but very little brain.	Ruppius, in Meissner's Forschungen, vol. iii. p. 240.
—	In a few days after the puncture.	—	Meissner, Die Kinderkrankheiten, vol. ii. p. 187.
Exaltation of sense of hearing, then improvement for 2 or 3 days; re-accumulation of fluid in a fortnight, gradual sinking after 2d puncture.	3 weeks after 1st puncture, 1 week after last.	Great vascularity of the membranes; softening of the brain; accumulation of fluid in the ventricles.	Mr. F. Cooper, Lancet, June 27, 1835, p. 405.
Convulsions ceased a few hours after 1st puncture; returned slightly before 3d and 5th. Health good till day before last puncture, then stupor; relieved for a time by puncture; 2 days after, quiet death.	115 days after 1st, 2 after last puncture.	Membranes pale, bloodless; septum lucidum torn; lateral ventricles formed one large sac, lined by thick flakes of matter, like pus or mucus.	Prof. L. A. Dugas, Amer. Journ. of Med. Sciences, vol. xx. p. 536.
Convulsions on 5th day; continued enlargement of head after each puncture; occasional convulsions, followed at length by coma and death.	62 days after 1st, 11 after last operation.	Fluid in the ventricles; great thinning of the brain; hole through falx and tentorium; cerebellum healthy.	Dr. J. B. Withridge, Am. Journ. of Med. Sciences, vol. xx. p. 538.
Improvement for 2 months, and progressing ossification; then improvement ceased, and head became quite as large as ever.	131 days after 1st puncture, 2 days after last.	Arachnoid engorged; fluid in all three ventricles; brain very soft; lymph at its base.	Dr. J. R. Smyth, MED. GAZ. vol. xxv. p. 83.
Convulsions came on, but ceased some weeks, till day before death, and child died in a fit.			

No.	Sex.	Age.	Duration of Disease.	Symptoms before Puncture.	Size of the Head.	No. of Punctures.	Quantity of Fluid.	Immediate Effect.
26	F.	10 d.	Con- genital.	Good at birth; at end of ten days head hot; child fretful; bowels disordered.	Head at birth twice natural size.	Two	$10 + 8 = 18$	After 1st puncture cold, faint, as though about to die; state after 2d not mentioned.
27	M.	8 m.	Began at end of 4th month	Health quite good up to 10th week, even now tolerably good; bowels regular; well nourished; eyes constantly rolling.	$22\frac{1}{2}$ inches in circumference.	Four	$20 + 23 + 22 + 19 = 84$	No peculiar effect.
28	F.	9 m.	Began in 3d month.	Healthy; in 15th week able to hold up its head, though very large; cried occasionally; continued well to 9th month, but head then too big to move.	$21\frac{1}{2}$ inches in circumference.	One	4, much drained away.	$\frac{1}{2}$ oz. of blood escaped; 4 days after, on passing a probe, 4 oz. of water.
29	—	8 m.	Began at 4th month	Screamed very often; slight convulsions; occasional vomiting; distortion of eyes downwards.	—	Two	$4 + 3 = 7$	Improved appearance followed immediately.
30	—	7 m.	Began at 2d month.	Good health.	$19\frac{1}{2}$ inches in circumference.	Two	$20 + 28\frac{1}{2} = 48\frac{1}{2}$	Pale, cried slightly after 1st; pale, did not cry after second.
31	F.	12 w. 1 d.	Began in 3rd week.	Fits of crying a fortnight after birth continued to recur, but without convulsions or strabismus.	$16\frac{1}{2}$ inches in circumference.	Five	$12 + 12 + 5 + 8 + 16 = 53$	Crying ceased; child seemed more comfortable.
32	M.	—	—	—	—	Five	$48\frac{1}{2}$	—
33	M.	—	—	—	—	Four	45	—
34	M.	—	—	—	—	Two	20	—
35	M.	—	—	—	—	One	8	—
36	M.	—	—	—	—	Two	22	—
37	M.	—	—	—	—	Two	17	—
38	F.	—	—	—	—	One	$7\frac{1}{2}$	—
39	F.	—	—	—	—	Four	33	—
40	M.	15 m.	Began at 5th month	Inward fits from birth; emaciation at a fortnight; increase of head and fits at 5 mo.; general health improved until 14 months, then fits more frequent, and child wasted more; but appetite very good.	26 inches in circumference.	One	16	Cried much; slight fit immediately after.

Subsequent Progress.	Date of Death.	Condition of the Brain after Death.	Authorities.
After 1st puncture, seemed improved; water re-accumulated at end of a week; after 2d, no improvement; at end of a fortnight after, head as large as before. Parents would not permit its repetition. Child wasted; died convulsed.	6 months 5 days after 1st, 5 months 12 days after last operation.	Fluid under dura mater; cerebrum so flattened that parts were undistinguishable.	Mr. Armstrong MED. GAZ. v. xxvi. p. 226.
Occasional vomiting; slight convulsions; head rapidly regained its size. 14 days after last puncture, moaning, crying, contractions of limbs, faintness, and difficult breathing came on.	7 weeks 3 days after 1st, 15 days after last operation.	Fluid within the membranes; left hemisphere almost totally destroyed, right greatly compressed; optic nerves diseased; left olfactory destroyed; right nearly so; cerebellum healthy.	Dr. Kilgour, Ed. Med. Sur. Journal, vol. liii. p. 365.
On day after the escape of the fluid, slight convulsions, eyes less distorted, but child began to sink, whined, then threw its arms about.	6th day after puncture.	Some congestion of membranes near puncture; brain quite white, very soft; ventricles immensely distended; cerebral substance seemed macerated, infiltrated with water; parts in ventricles undistinguishable; nerves at base soft; cerebellum large, soft; cavity in its centre; no trace of arbor vitæ.	Dr. Schaeffer, Casper's Wo- chenschrift, Aug. 19, 1837.
On evening of 4th day after first tapping, child grew dull; respiration hurried, and death took place before midnight.	4th day after 1st, 3d after 2d puncture.	—	Dr. Watson in Tweedie's Lib. of Med. p. 147.
After 2d puncture, cerebral symptoms came on, head being smaller. Head regained size in 10 days after 1st puncture.	24 days after 1st, 24 after 2d puncture.	—	Malgaigne, l'Expérience, Nov. 19, 1840.
Occasional fits for 10 days after 2d puncture; then frequent screaming, and increasing weakness, without fits, till 2 days before death, when they returned frequently.	15 weeks after 1st puncture, 5 weeks after last	Twenty-nine ounces of clear fluid in ventricles, which were lined by a brownish mucus; septum lucidum thickened; small tubercle at decussation of optic nerves.	Dr. Cold- stream, Edin. Monthly Jour. of Med. Sci. April, 1841.

Daily fits for 4 days, with more sluggish condition than before. In 7 days, head as large as before the puncture, to the repetition of which parents would not consent; refused food; diarrhoea for 7 days; emaciation, increased weakness; death.	17 days after the puncture.	Seventy-five ounces of fluid in the ventricles, and infiltrated into brain, which was split up into layers forming several distinct pouches; the walls of these pouches were not formed by false membrane, but were all continuous with the corpus callosum, into which their fibres might be traced; cerebral substance at base had a jelly-like appearance; optic nerves much spread out; fluid infiltrated between fibres of cerebellum	Dr. Con- quest, Lan- cet, March 17, 1838; and Med. Gaz. vol. xxi. p. 967.
			The writer.

In 30 of the above 40 cases, the interval which elapsed between the performance of the operation and the patient's death is stated; and it appears that the deaths after the first puncture were as follows:—

Deaths.	Average duration of life after the puncture.
6 within 4 days	53 hours
6 „ 14 days	6 days, 8 hours
3 „ 1 month	20 days, 16 hours
9 „ 3 months	56 days, 10 hours.

Of the remaining 6, only 1 survived the puncture 6 months; and the average duration of life in each of these was 3 months, 4 days, 12 hours. In 18 of these patients, the operation was performed more than once; but in no instance did the children survive the last puncture more than 35 days, while the average duration of life was 12 days, 22 hours.

The instances, then, in which life was prolonged by the operation appear to be very few, and the cases in which any reasonable prospect of the patient's recovery existed after a week had elapsed from the first performance of the puncture, are still fewer. The table shows that sometimes the puncture was followed by an almost immediate aggravation of the cerebral symptoms, and by death. Usually, however, a degree of apparent improvement followed the puncture, but the fluid soon collected again, and less marked relief followed the second operation. With its repetition the quantity of fluid increased, and while the size of the head continued undiminished, or even grew larger, the body of the patient became emaciated; and death either took place from exhaustion, or cerebral symptoms came on, and life was terminated by coma or convulsions. The termination of an ordinary case of chronic hydrocephalus is usually preluded by low fever, with general emaciation, to which fatal coma or convulsions succeed; and precisely similar are the symptoms noticed in the cases in the second table, except that the signs of cerebral disturbance appeared with an intensity which, but for the mechanical injury to the brain, they would, probably, not have presented.

If the symptoms observed during life yield little encouragement to resort to the operation, the appearances disclosed after death afford a powerful argument against it. An account is given of the post-mortem examination of 26 cases.

In every instance fluid, sometimes in considerable quantity, was contained within the ventricles or in the cavity of the cranium, and the substance of the brain was softened and attenuated. But, in addition to these appearances, there existed, in 16 cases, serious organic disease or malformation of the brain itself, though no symptom during life had betrayed the existence of a condition which mechanical interference could only aggravate.

The above-mentioned facts have led the writer to form an opinion unfavourable to the performance of puncture of the head, as a means of curing chronic hydrocephalus. Other points of interest might be elicited by an examination of the tables, but it would not be possible to dwell on them within the limits of a single paper\*.

#### THE MEDICAL STATISTICS OF HASTINGS,

By JAMES MACKNESS, M.D.  
Physician to the Hastings Dispensary.  
(For the Medical Gazette.)

THE population of the borough of Hastings, at the last census, was upwards of 11,000. It enjoys one of the most genial climates in Britain, completely sheltered as it is by hills, and some of the highest land in Sussex. It is completely protected from the north and east winds, and only open to the south and south-west: its mean annual temperature is about 51° Fahrenheit, but it is particularly characterised by the equality of its temperature during the winter and spring months: it is in a great measure also free from those cold and dense fogs which are the bane of the English climate: this arises, in a great measure, from the light and sandy character of its soil, absorbing all humidity; at the same time a smaller annual quantity of rain (28 inches) falls at Hastings, than most other places on the southern coast, while the number of days on which rain falls during the six months of winter and spring are only sixty-three. From the superior altitude, and more exposed situation, of many of the buildings, the opportunity is also offered for invalids to select a more bracing or sheltered abode, as circumstances may require.

\* At p. 127 ante, col. 1, line 4 from bottom, *delete* "now"; and two lines lower, after "dangerous," insert "it is nowhere alluded to as a novelty."

Possessing these natural advantages, Hastings has long been selected, and celebrated, as a resort for patients suffering from affections of the chest, and tubercular disease in all its forms, but no facts have hitherto been collected to prove its salubrity, and only a vague general opinion has been formed that it is a healthy place: the state of medical science however demands more decisive evidence, for that able pathologist, Louis, has acknowledged that every previous theory which he had formed upon the statistics of diseases, or the symptoms of disease, he found incorrect when put to the test of experience. Unless the statistics of disease and death among the inhabitants of Hastings themselves, will prove the superiority of its climate, every argument adduced in its favour can be of no avail. In order therefore to ascertain how far the received opinion as to the health of the town was correct,

I have carefully examined the books of the Hastings Dispensary, during the twelve years it has been established, and classed those entries where the diseases had been registered according to the plan in the report of the Registrar General, whose first and second reports I have also used as comparisons. This collection comprises nearly 8,000 cases of disease which have received medical and surgical treatment at this institution. I have also taken advantage of and classified all the deaths, from the Registrar's book of deaths, which have occurred in the borough of Hastings, from all causes, during the four years the Registration Act has been in operation. From these united sources I am enabled to form some opinion as to the statistics of disease and death, and the prevalence or infrequency of various diseases; also to make a comparison between the salubrity of Hastings and other places.

NOTE.—The Borough comprises the whole of Hastings and St. Leonard's on Sea. The population is upwards of 11,000.

The first column contains the result of twelve years' practice of the Hastings Dispensary. The second column contains the amount of deaths, from all causes, in the Borough, during four years' registration.

						6			865

Only seven cases of typhus fever have occurred in the practice of the Dispensary during the twelve years, and only six cases of death are registered as the result of this disease for the whole of Hastings. Whether these six deaths were caused by idiopathic typhus, or whether the patients were suffering from some other diseases which had reduced their strength, and thus rendered the body in a fit state for the supervention of typhoid symptoms, I am unable to learn. I should, however, think the latter supposition to be the most probable, considering

the very few cases that have occurred in the Dispensary practice. During the past year, although 1250 persons were admitted patients to this institution, not a single case of this fever was amongst them.

According to the report of the Registrar-General, the proportion of deaths arising from typhus fever in the whole kingdom is about one for every sixteen of those who die from other causes: the mortality of Hastings has been only six cases out of 865 deaths, or only in the proportion of one for every 144; so that this fatal and dreadful

malady has been nine times less frequent at Hastings than the usual average in other parts of England. It will be seen by the table that upwards of 400 cases of simple continued fever have been under medical treatment at the Dispensary during twelve years. It appears to me that one of the most fertile sources of this disease had its origin in, and was propagated by, imperfect drainage.

Formerly, an uncovered brook, called "The Bourne," acted as the common sewer of a great part of the town; and although care was taken to wash out this brook frequently by means of a stream of water let in by a floodgate from a reservoir reserved for the purpose, yet the emanations arising from partially decomposed animal and vegetable matter, in a densely populated neighbourhood, were any thing but conducive to the health of the inhabitants. The Bourne brook was covered over in the year 1834, since which period this disease has gradually decreased, and almost entirely disappeared. In the year 1840, there were only thirteen cases; and during the last year only three cases of this disease occurred in the Dispensary practice.

Upwards of 150 cases of ague have also been under treatment at the Dispensary since its establishment, and although a number of these cases came from the neighbouring villages, several of which are situated near the marshy districts, where ague is prevalent, yet many of them occurred amongst the inhabitants of the town; and doubtless the principal source of this disease also may be attributed to the same influence as that alleged as the cause of continued fever: this is, in some measure, proved by the corresponding diminution in the number of cases. During the last year, even with a much greater number of patients, only seven cases of ague were admitted. The town had no visit from that frightful and fatal disease Asiatic cholera, when so many sea-ports suffered from its ravages; although the poverty of a very large part of the population of Hastings, their crowded dwellings, and poor diet of fish, upon which they principally subsist, are circumstances which especially rendered the inhabitants liable to such a visitation: and here I would remark, in considering the statistics of a fishing-town, that

fishermen, although a hardy race, are more liable to diseases than any other class of the community. From a statistical memoir upon the influence of various professions on the health and mortality of mechanics and artisans in the prime of life, founded on the Tables of the Institution for Sick Mechanics at Wartsburgh, in Germany, from 1786 to 1831, by Dr. C. H. Fuchs, Professor of Medicine, and published at Berlin in 1835, the sickness and mortality of fishermen and sailors were found greater than among other trades. This is supposed to arise from the irregularities of their earnings, not affording them, at all times, a proper supply of wholesome food, as well as from their continued exposure to cold, wet, and various accidents.

It is calculated that between a fifth and sixth part of the entire number of deaths in temperate climates arises from consumption. Dr. Shuttuck, in the Vital Statistics of Boston (United States), says, sufficient facts are known to show that from one-fourth to one-seventh of all the deaths in the northern and middle states of America, and perhaps of the whole world, are caused by consumption.

The annual returns of the Registrar-General show that a fifth part of the mortality of England is caused by this disease.

Sir James Clark considers that a sixth of the deaths in Britain is decidedly caused by pulmonary consumption. And in Italy itself, and the south of France, it is well known that the proportion of deaths from this cause is, if anything, greater than it is in England.

To ascertain, with any degree of certainty, the number of deaths which arise from this cause amongst the inhabitants of Hastings, it is absolutely necessary to inquire minutely into every individual case that may be registered as having occurred within the limits of the borough. Unless this inquiry is carefully made, it is impossible to obtain a result at all approaching to truth; as from the great number of invalids of this description collected from all parts of the country, many of them in the last stage of consumption, it is only reasonable to expect that a large proportion of deaths from this disease will consist of those who have been injudiciously brought from a dis-

tance, many of them at a time when the case was already hopeless, and who were literally sent hither to die. But even with this large addition to the numbers, the average of deaths from this cause is not greater than in other places: and when the inhabitants are carefully distinguished from strangers, a distinction which I have had the opportunity of making, the average is found to be so much smaller than the usual amount elsewhere, that it must at once satisfy every reflecting person of the suitableness of Hastings for consumptive patients.

During the four years the Registration Act has been in operation, the entire number of deaths entered in the Registrar's books as occurring at Hastings and St. Leonard's, under the heads "Decline and Consumption," is 161 out of 865 deaths from all causes. Now this is hardly one-fifth of the mortality, or scarcely so high as the usual average for the whole of England, as proved by the reports of the Registrar-General.

But of this number 70 were entire strangers to the town, and came from a distance; and these being deducted from the 161, the balance left is only 91 deaths from this cause among the inhabitants themselves, or rather more than one for every nine from other causes: thus amounting to scarcely more than one half of the usual mortality from consumption.

But even the above numbers ought to be greatly lessened, as it is well known that nurses, and that class of persons who generally certify the death to the Registrar, are in the habit of calling every disease in which there is great wasting of the body, a decline; and therefore a great part of the above 91 cases were assuredly not tubercular phthisis. Some, indeed, which came under my own observation, were thus improperly classed. For instance, at one season of the year, a great number of persons employed in the fishing make an annual excursion to Plymouth for several weeks, to catch mackerel, during which period they are necessarily much exposed to the weather, and from this cause often have severe attacks of inflammation; at the same time, being far from home, and constantly employed, they seldom have proper medical treatment, and as a consequence they return home with dis-

ease already too far advanced for medicine to be of any avail.

During the last year, two fine fellows came under my care, as Physician to the Hastings Dispensary, precisely under the circumstances above named; one of them had had pleurisy, the other pneumonia. Both cases were too far advanced for medicine to be of service, and both gradually sunk from the effects of the disease; yet both these cases were entered as consumption, because they were chest affections; and they form a part of the 91 cases, although neither were really affected with tuberculous disease. It may be alleged that all registered reports are open to the same objection; but the following is another and greater source of fallacy, viz., that still more important class who, having resided several years at Hastings, because suitable for their health, are considered as inhabitants, but who originally came from other places, with a constitution highly predisposed already to tubercular disease.

The climate may have its effect in prolonging their lives, but not in restoring their ruined health; and thus they also contribute to swell the list. So that were all the cases not tuberculous, distinguished from those truly tuberculous, and were all who have not been born at Hastings separated from the native population, I am inclined to believe that consumption would be even less than one-half as prevalent amongst the inhabitants of Hastings as at other places.

The number of cases of hernia, 276, may perhaps appear large: most of these applicants were supplied with trusses; and it should be taken into consideration that fishermen wear out trusses very quickly, the springs becoming rusty from sea water, and the men are constantly stooping and lifting heavy weights in their employment; and if we refer to the comparative frequency of hernia according to sex and age, and also relative to the population, by F. Malgaigne (*Annales d'Hygiène publique*, July, 1840) for Paris, taking the rich and poor at the age of 21—

The poor	1 out of 28
„ middling classes	1 out of 38
„ rich	1 out of 37.

It was found also more rare among the mountainous or hilly districts than in

those of the plain, and less frequent in towns than in the country; and if we take the male population of Hastings at 1000 who would apply at the Dispensary for trusses, and allow a new truss every year for each case, it would only be one case of hernia for every 33 of this class of the population—or less than the average proportion of the poor at Paris.

During the past year, the only cases of much interest which have occurred in my own practice were a case of aneurism of the arch of the aorta, and the following case of extensive disease of the brain.

On the 5th of Jan. 1841, Richard Salmon, fisherman, applied for admission to the Dispensary: his general appearance healthy, habits temperate: he complains of constant acute pain in the left temple, from which he has suffered more or less during the last two years. States that he has been repeatedly under medical treatment, has often been bled and blistered for it, sometimes with, sometimes without benefit. He says the pain had been somewhat easier for some time past, until the 28th of last month, when, being at sea, and the weather being very cold and stormy, he experienced a sudden and severe return of the pain; was seized with cold and shivering: he came ashore, and when he arrived at home, he was very faint, sick, and entirely lost all power of moving his limbs, or, as he expressed it, "he was so benumbed with the cold, that he lost his feeling." Upon being put into a warm bed, and some stimulants being given him, he gradually felt better. At the present time complains of constant pain in the left temple; pulse natural; appetite good; tongue clean; bowels rather confined: says that both his temples often swell; and points to one part which he says is swelled at present, but which, upon careful inspection, presents no unnatural elevation. No loss of sight; no defect of memory or speech; and although he is not intelligent, he appears capable of exercising his mental faculties equally well with the generality of his class. The only peculiarity in his appearance is, that his left eye appears to project more than natural. No febrile symptoms being present, the carbonate of iron was ordered, upon the supposition that the pain was of a neuralgic cha-

racter; the bowels being kept open with magnes. sulph.: the symptoms, at first, were relieved by this treatment; but after a few days he complained that the pain was equally, or more severe, and at the same time the pulse was a little increased in frequency and fulness.

Leeches to be applied to the temples, blisters alternately behind the ear and nape of the neck.

Feb. 1st.—Pain still continues; cannot get any sleep; complains of shivering and continual feeling of cold; slight alteration in his speech; does not so quickly comprehend questions put to him; his wife says he is restless during the night, with slight convulsions; pulse weak and slow; bowels costive.

Mist. Sennæ Co., pro re nata; a seton to be put in his neck, and blisters behind the ears.

March 1st.—The above means have been continued without intermission, and without benefit. He is now partially comatose, but when roused still complains of the pain; pulse 70, very weak; bowels still costive; seton discharges freely.

Capiat. Pil. Hydr. Chlor. Co. gr. iij.; ter die.

After a few days, his mouth was affected with the mercury, but without any perceptible improvement in his symptoms, while the difficulty of speaking, and prostration of the mental powers, continued to increase. All active treatment was therefore omitted: he, however, continued to linger, with the powers of life gradually diminishing, until the 28th of August. During the last few days, the sphincters ceased to perform their functions, and he lay in a complete state of coma, only interrupted by convulsions, during a paroxysm of which he died.

*Autopsy, 36 hours after death.*—On removing the calvarium, the inner table of the skull was found exuding, rough, and covered with sharp-pointed elevations. This was particularly the case on the squamous portion of the temporal bones, the upper part of the right parietal bone, near the sagittal suture, and both the orbital plates of the frontal bone: so sharp were some of these pointed elevations that a very slight pressure of the fingers would have been sufficient for them to have

lacerated the skin. There was great adhesion between the dura mater and the skull, particularly on the left side, where the membrane was also much thickened and inflamed. On attempting to separate the dura mater from the arachnoid, the two were found strongly adherent, and this last membrane was studded with minute specks of apparently albuminous matter. Under the squamous portion of the left temporal bone, the surface of the brain, to the extent of a square inch, was covered with pus, but the suppuration did not extend into the substance of the brain. Upon cutting into the substance of the left hemisphere, the colour was paler than usual, and much softer than natural: the ventricles were full of fluid, but exhibited no abnormal appearance. Upon removing the brain from the skull, the whole of the base of the anterior and middle lobes of the left hemisphere, and the middle lobe of the right, were in a state of ramollissement. The supra-orbital plates of the frontal bone, and the greater wing of the sphenoid bone, were also found to have the same roughness, and studded with sharp points in the same manner as the calvarium.

---

ON THE  
COLOURLESS CORPUSCULES,  
AND ON THE  
MOLECULES AND CYTOBLASTS  
IN THE BLOOD.

By WILLIAM ADDISON, F.L.S.

[Continued from Vol. 1, 1840-41, pp. 477 and 669.]

CASE X.—M. M. R., a stout young woman of dark complexion, aged 20, is hoarse, with slight cough and pain in the side. Several of her relations have died consumptive.—V. S. ad 3vj.

In five minutes after the bleeding there were two or three purplish patches on the surface of the blood. I removed a thin film of coagulated fibrine from one of them with the point of a needle: below it the liquor sanguinis was still fluid. Having lightly touched this fluid with the point of a finger, I transferred a large and colourless drop to a slip of glass. Great numbers of pale globules, or colourless corpuscles, were floating in it, visible to the unassisted eye; through a Coddington lens the absence of all colour in them was still

more apparent. Having placed another slip of glass upon the first, inclosing the fluid between them, I submitted it to an examination by the microscope. I found the colourless corpuscles somewhat larger than the red corpuscles with which they were compared, measuring from  $\frac{1}{800}$  to  $\frac{1}{500}$  of an inch in diameter.

I observed at the same time that the fluid, i. e. the liquor sanguinis, contained a great number of extremely minute molecules or granules, varying in size (Fig. 1, *a*), the largest of them being at least eight or ten times less than the colourless corpuscles, and they were in much greater abundance.

Whilst examining these minute bodies, I observed the coagulation of the fibrine commence. Exceedingly delicate and perfectly cylindrical filaments or fibres crossed the field of the microscope; they gradually increased in number, intersecting one another in various ways, and at length formed a complete net-work, in the meshes and angles of which the molecules and colourless corpuscles were collected and drawn together. Many molecules were situated, at distant intervals, along the course of the filaments, and the diameter of the filament being less than that of the molecules, they formed nodules upon it (Fig. 1, *b*).

In several places where the fibrine, from the unevenness of the surfaces of the glass, was abundant, the filaments were so interlaced with each other, and with the molecules and colourless corpuscles, that it was almost impossible to discriminate them from each other (Fig. 1, *c*). In other places, where the fibrine was less copious, the cylindrical character and delicacy of the fibres forming the net-work was exceedingly conspicuous.

This young woman had a slight muco-purulent expectoration, in which I found pus corpuscles of all sizes—molecules or granules, and epithelium cells.

A great number of the molecules or granules were floating independently in the mucus, and exactly resembled those seen in the blood. There were others in the interior of the pus corpuscles, situated either towards their centre, or attached to their circumference, both inside and out.

In the epithelium cells there were also a great many molecules or granules, some situated towards the margins of

the cell, others surrounding the large nucleus in the centre (Fig 2, *a*, *b*).

CASE XI.—J. J., a stout muscular man, aged 40, ill four days with acute rheumatism; wrists and ankles swollen, and very painful; countenance sallow. V.S. ad 3xxiv.

Blood drawn into four cups. Before the end of the bleeding, that drawn in the first cup exhibited a thick layer of liquor sanguinis of a yellow colour; and at the termination of the operation the blood, in all the others, had the same appearance.

The liquor sanguinis, at first a clear yellow viscid fluid, soon became turbid and mottled; in a few minutes flocculi were floating in it, rendering the fluid opaque.

After removing a thin pellicle of fibrine from the surface, with a needle, I gently touched, with the point of a finger, the fluid beneath, and placed a colourless drop between two slips of glass. On submitting it to the microscope, I found a great number of colourless corpuscles, some of them containing in their interior several exceedingly minute molecules or granules (dark specks); others with one, two, or three, larger molecules or granules (bright).

There were also floating in the fluid great numbers of loose or independent molecules, varying in size, the largest being at least eight or ten times smaller than any of the colourless corpuscles.

These minute molecules or granules had the appearance of dark specks, or bright ones with a dark circle, according to their approximation to the focus of the microscope.

The coagulation of the fibrine had not at this time commenced in the drop of liquor sanguinis under examination; very soon, however, the fibrinous filaments made their appearance, which, gradually increasing in numbers, crossed and intersected each other at various points; the molecules at the same time congregated together in various irregular groups. The filaments were not composed of strings of molecules; they were uniformly cylindrical, and formed a complete net-work during the examination.

As before, in those places where the fluid, from the unevenness of the surfaces of the two slips of glass, was abundant, the number and intricate interlacements of the fibrinous fila-

ments, inclosing and drawing together the molecules and colourless corpuscles, gave rise to the same confused appearance as is seen in any thin pellicle of fibrine; such, for instance, as first forms on the surface of buffed blood (Fig. 3).

Four days after, the man was much better; free from pain; pulse soft, 84. I should not have bled him again, but being a strong subject, and wishing to continue my investigation, I took a tea-cupful more; and immediately before the subsidence of the red corpuscles, and previous to the formation of the fibrinous pellicle, I removed a small drop, and examined it by the microscope. I found numerous red corpuscles, a great many colourless corpuscles, and at least twenty times as many molecules or granules.

I immediately added to them a little dilute acetic acid, which instantly destroyed the colour of the red corpuscles, and rendered them almost invisible; whereas the colourless corpuscles stood out in still more prominent relief, and the molecules or granules in their interior were rendered exceedingly conspicuous. In some there was one, in others two, three, or four, bright granules, precisely similar to those floating loosely in the fluid (Fig. 4, *c*).

The acid, after a few seconds, evidently had the effect of liberating the molecules or granules from the interior of the corpuscles, but it had no influence upon the molecules themselves, otherwise than rendering their presence in the interior of the colourless corpuscles more evident.

The general character of these colourless blood corpuscles, the existence of well-marked molecules or granules in their interior, and their behaviour on the application of dilute acetic acid, identify them with the pus-globules of Gulliver.

But, as the term pus denotes an abnormal and *extravascular* product, it seems inappropriate to apply the term pus corpuscle to an *intravascular* corpuscle circulating in the blood, and the existence of which, *within certain limits, is perfectly normal*. I have, therefore, retained the term colourless corpuscle.

Independently, however, of this consideration, the colourless corpuscle of the blood has the structure, and agrees in every particular with Schleiden's

"cytoblast," or the "nucleus" of Valentin and Brown.

There is, indeed, some difficulty in arriving at the true meaning of the various terms, molecules, granules, nuclei, and nucleoli, with reference to the cytoblast and the cell.

I have referred to all the authorities at hand for assistance, without finding a satisfactory description.

"The abundant gum of nascent parts of plants—such as the youngest albumen of a seed—when examined by the microscope, is seen to be turbid from the presence of minute molecules. Soon larger granules are also observed in it. Around these granules (how many, is not stated), by a kind of coagulation, larger bodies are formed—the cytoblasts—in which the above-mentioned granules are visible, as nuclei\*." Two, three, or more granules, thus form the nuclei of the cytoblast. But this account does not agree with the following taken from the same work:—

"In a pre-existing homogeneous substance, which contains the nutritive matter for the future tissue, granules appear: some of these acquire a larger size than the rest, and assume the form of nuclei, containing one or two, and sometimes three or four, smaller opaque particles, which Valentin has named nucleoli†."

Here the granules are described as assuming the form of nuclei, and as enlarging and containing nucleoli. Again, "when the cytoblast has attained its full size, a small vesicle appears on it. This enlarges and becomes the cell, in which the cytoblast is for a period still visible, either attached to its walls, or free in its cavity." (p. 47.)

"The primary cell, both in vegetables and in animals . . . contains within it another body—its nucleus . . . the nucleus containing one, two, three, or four nucleoli . . . The nucleoli are first formed, and organic matter becomes aggregated around them to constitute the nuclei. The nucleus having attained a certain size, the cell begins to be developed, and when first recognizable, is so small that the nucleus occupies nearly its entire cavity. As the cell enlarges, the nucleus remains

attached to its wall at one side." (p. 398).

"Cytoblast" and "nucleus" are synonymous terms; and yet the smaller granules within the cytoblast are called nuclei; while the granules within the "nucleus" are termed nucleoli.

I agree with Dr. Carpenter, that it is preferable to adhere to the original term "nucleus," as the use of the name "cytoblast" involves a theory, with respect to its function or office\*, which is by no means settled. The following, then, appears to be the order of the phenomena which attend the formation of the primary cell.

In the nutritive fluids of vegetables and animals, minute molecules or granules are the first visible particles. Around two, three, four, or more of these granules, the organic matter coagulates and forms the nucleus. Upon or around the nucleus more organic matter aggregates, forming the primary cell; and, as the cell enlarges, the nucleus is seen either attached to the wall of its cell or in its interior, with the granules or nucleoli within it.

CASES XII. XIII. and XIV.—M. C., a woman aged thirty, poorly with a slight cold, going about, and in every other respect quite well. Having pricked the back of the hand with the point of a needle, I received a small drop of blood on a slip of glass, and diluted it with a little weak acetic acid. I found in it several colourless corpuscles, with very distinct granules in their interior.

J. A., a man, aged forty, quite well. I proceeded as in the last case, with precisely the same result.

C. B., a young woman, aged nineteen, taken ill a month ago, with cold and sore throat; for which she lived low, and took physic. She then had a breaking-out about the mouth, with headache. She now applies for advice for inflammation about the finger. The hand is much swollen, and very red. I cannot discover any fluctuation or gathering. The pulse is quick and thrilling. Pricked the skin over the knuckle, where it was extremely tense and red, and placed a drop of blood diluted with the weak acid under the microscope. There were hundreds of large colourless corpuscles, with well-marked granules in their interior.

\* Müller's Physiology, p. 47.

† Op. citat. p. 398.

\* Principles of General and Comparative Physiology, p. 313.

Fig. 1.

Fig. 3.

Fig. 4.

Having received another drop of blood on the slip of glass, I diluted it with a little saliva, which does not so soon destroy the colour of the red corpuscle. I then compared the two corpuscles, and I found the colourless corpuscle at least three, some were four, times the size of the red corpuscle. They appeared rough, or granulated, but did not display the distinct granules until after the addition of the acid. It is well known that, in the blood circulating in the web of a frog's foot, there are round colourless corpuscles, termed lymph globules, which have molecules or granules in their interior.

These lymph globules are strictly analogous to the colourless corpuscles in human blood, not only in their general character, colour, and structure, as developed by the microscope, but by their accumulating to an extraordinary amount in all the vessels in which inflammatory action has been excited.

I have made a great many experiments upon this subject, applying a variety of stimuli to the web. Different stimuli produce different effects upon the motion of the blood, and upon the calibre of the vessels; even the same stimulus produces different effects in different individuals. Some stimuli empty the vessels of red corpuscles; others produce congestion, and make them redder. A weak stimulus causes pulsations and oscillations in the capillaries, or retrograde motions; but amidst all the varieties of motion I have seen, there is one constant and uniform effect which I have never failed to observe, and this is *an immense accumulation of the lymph globules in all the vessels upon and around the spot to which the stimulus had been applied.* [I reserve the details of these experiments for a future communication.]

Minute molecules or granules are abundant in all animal and vegetable structures. They have been repeatedly observed, and figured by numerous writers, in the epithelium of mucous membranes, in the ciliated cylindrical epithelium of the bronchi, in chyle, in pus, and in the ova of animals and vegetables. The bodies of many animalcules are entirely filled with them, and when isolated they frequently exhibit very active motions.

I am not, however, aware that similar molecules have ever before been

noticed in human blood; and their existence in this fluid has an important bearing upon the prevailing doctrines, as to the origin of all organized structures from cells, these cells originating from nuclei, or, as they are generally designated, after Schleiden, cytoblasts.

[In the 18th No. of the British and Foreign Rev. there is a figure (1, plate 2), after Schleiden, representing the first stage of the formation of cytoblasts in organizable mucus. This figure affords a correct idea of the appearance presented by the liquor sanguinis of the blood when examined by the microscope before the coagulation of the fibrine, in the way I have pointed out].

Dr. M. Barry, in a paper lately presented to the Royal Society on Fibre, states, "that the nucleus of the blood corpuscle, in some instances, resembles a ball of twine, being actually composed, at its outer part, of a coiled filament;" and he "has seen the filament unwinding itself\*." If this account should be verified by further observations, the varying dimensions of the blood corpuscles (red and colourless?) must depend upon the length of the filament entwined around the nucleus or central molecules.

The exceedingly delicate fibrinous fibres which I have described, were perfectly independent either of the red or colourless corpuscles, or of the molecules. They did not proceed from the unwinding or uncoiling of any filament connected with the structure of either of them.

ON  
ARTIFICIAL CLIMATES,

FOR THE RESTORATION AND PRESERVATION  
OF HEALTH : TO BE CONSIDERED UNDER  
TWO HEADS.

I. *The atmospheric treatment of the lungs.*

II. *The atmospheric treatment of the lungs and skin.*

BY JULIUS JEFFREYS, F.R.S., &c.

[Continued from p. 48.]

*On the atmospheric treatment of chronic affections of the lungs.*

WITH a view to establish the great importance, in chronic affections of the lungs, of an atmospheric treatment directed to the organ itself, it will have sufficed to examine those symptoms which are, more than others, dependent upon atmospheric influence, while they are the most distressing to the sufferer. At the same time, it cannot be doubted that all other symptoms must be aggravated by a cause capable of producing, or of materially increasing, those of chief distress. Furthermore, it has appeared proper not only to solicit a minute attention to the whole extent to which the air may be affecting any symptoms, but to maintain that such attention should be afforded before medicinal remedies are employed for allaying local irritation, so far as it can be shown to depend on the air inhaled. While this position may be rested immovably upon the soundest principles in medicine, the argument against the employment of soothing medicines prior to trying the most soothing atmosphere, does not, of course, include those remedies which form the systematic treatment of the disorder itself.

It will often happen that a certain state of the air, however trying, will give rise to no symptoms of uneasiness, unless some morbid excitability exists in the chest; and again, we may frequently find causes conducive to such excitability to produce no symptoms of distress if the atmosphere is of a soothing character, or even moderately temperate. Thus, in the case of asthmatic persons, and others, and of children with worms, both atmospheric and gastric irritation have often to act together in order to produce dyspnoea. In such cases, by administering to the stomach anodyne medicine, or to the lungs

genial air (in the one case suppressing their sensibility to the atmospheric cause of irritation, in the other removing the cause itself), we may produce an abatement of the chest symptoms without the employment of remedies for the gastric disorder; but we shall, of course, do little towards affording permanent relief, unless proper medical treatment be directed against the malady which produces the pulmonary irritability; and in other cases, where the primary disease is seated in the chest itself, it is not for a moment doubted that the main treatment should be directed against the intrinsic causes of the local affection. The foremost importance of this systematic treatment is readily, and, as a matter of course, admitted; but leaving out of the question nostrums and hidden specifics, swallowed by so many persons to their ultimate injury, it is the temporary allaying of local symptoms, even by well-devised medicines, prior to the endeavour to soothe the lungs by administering to them a perfectly genial air, against which my argument is throughout directed. The ground taken is good, whatever are the medicines employed; but its stability becomes obvious to any person when they are opiates, or other drugs of a narcotic class. A patient himself cannot fail to discern aright the choice to be taken between the two courses; if in the one the lungs can be soothed by removing altogether the *extrinsic* cause irritating them, through the administration to the organ itself of a perfectly genial air, while, in the other case, the lungs are acted upon, not directly, but by medicines administered to the stomach; and these having no power over the atmospheric irritant, but merely suppressing, or deadening for a time the sensibility of the lungs to its influence.

As this circuitous action on the lungs, through the medium of the stomach and brain, cannot be effected without some trial to the nervous system, and as it is the nature of this system, when thus frequently acted upon, to grow less impressed by the agent, while the irritable part tends towards a greater dependence on it, we commonly find a growing need of anodynes in chronic cases. Whereas, if the soothing can be effected by a modified atmosphere, the subsidence of the morbid irritability is of a natural kind; con-

sequently its tendency to renewal continually diminishes. Upon every ground, then, the latter must be considered the preferable course. That *the Theory of Medicine* upholds this view cannot, I think, be questioned, neither can its importance, where so much suffering and disease are concerned.

We are thence led to inquire whether we have at command any efficient means for producing the desired modifications of the air respired by the lungs, without involving the skin in the same atmosphere; and whether the employment of such means have led to any practical, at all corresponding with the promised, results. On pursuing the inquiry, it will appear that measures of two different kinds seem to be indicated for invalids under different circumstances.

Prior to this inquiry, it will be right to consider the indirect part which the atmosphere plays in causing or aggravating affections of the chest. It will suffice to refer to its action generally; so as not to occupy the medical reader with a detail of particulars with which all are familiar.

We find ungenial conditions of the atmosphere to produce their indirect effects upon the chest, when in a delicate or diseased state, chiefly in three ways—first, by depriving an invalid of fresh air, exercise, and the healthful play of the spirits, through confinement within doors, if not to one or two apartments. Secondly, by chilling the surface of the body, and thus distressing the lungs, in part through their sympathy with the skin, and partly by disturbing the balance of the circulation, and also by robbing the body of warmth needed by the lungs. Thirdly, an ungenial air acts less perceptibly, and more gradually, yet to a serious extent, by compelling many to load themselves with clothing, especially in bed and when out of doors, and often with clothing which scarcely allows the air to circulate at all over the surface of the body.

With respect to the first; confinement within doors is so injurious that physicians have long found it necessary, in many cases, to require patients to go out at all hazards, exposure to an ungenial atmosphere being the smaller evil of the two; especially where a tendency to pulmonary disease

is accompanied with debility of the stomach or liver, or an easy depression of the spirits. In cases of chronic bronchitis, and of laryngitis, when once the weather has gained, as it were, the upper hand of the system, it is surprising to observe to what an extent it often causes close confinement to become the sole instrument preventing recovery. In a delicate state of the chest, arising from derangements of health quite of a temporary kind, and which would pass away with these its causes, a searching atmosphere may be found, in no small number of cases, to be the sole cause perpetuating the delicacy, by not allowing the system time to gain vigour, and its various functions to acquire that healthful play without which the local irritability cannot subside. Hence we often meet with persons who have been confined, throughout every winter, for six, eight, or even twelve years, and who, could they have been enabled to weather the climate for two or three successive years, might have become nearly, if not quite, as superior to atmospheric influences as the generality of persons in health; a fact which has of late been established by the evidences of numerous cases. And in pulmonary consumption how often does the constitution rapidly break down from the time that the invalid is entirely confined at home!

Secondly: The indirect action of the atmosphere upon the lungs, by chilling the surface of the body, is a cause of disease so powerful and frequent as to be overlooked by none, and to have met with much attention on the part of the profession. The reason why pulmonary invalids suffer much from chilliness on the skin is sufficiently obvious to the pathologist. If requiring discussion it should take its place under the second division of my subject—the atmospheric treatment of the lungs and skin. At the same time a few remarks upon it are called for here, from its connection with measures for affording ease to the lungs. Cold on the surface causes distress in the lungs, not only, in the first instance, by sympathy of feeling and action between the skin of the surface and of the lungs—and next, by tending to overload the lungs with blood driven from the surface, but it also acts to an important extent by withdrawing more animal heat from the body than can be spared without

suffering in the lungs, which require so large a stock at their own surface to meet the demand upon them of the respired air. It has to be borne in mind that while the production of animal heat, depending as it does upon vital causes, is often greatly diminished in a delicate, and especially in a diseased, state of the lungs, the demand of the respired air upon the membrane for warmth remains the same, since it, in conformity with physical laws, is unvarying. It becomes obvious, then, that if an equal quantity of warmth continues to be drawn from the surface of the body, not only will it be chilled, but the similar demand upon the lungs must chill the membrane lining the air passages. Now we have every reason to conclude that this cannot take place to any extent without causing symptoms of uneasiness and afterwards of disease.

Thirdly: We have to notice the injurious effect of the necessary remedy for the former—namely, a large quantity of clothing on the surface. This also belongs to the other division of my subject; but it may be allowable to remind the reader of the conclusions to be drawn from the numerous inquiries into the reciprocal action of the lungs and skin, which show the necessity for healthful action in the former, of a proper performance of the functions of the latter. There is reason for thinking that the clothing, which in a delicate state of health is often necessary, does itself tend to suppress the action of the skin, and the production of animal warmth. The curious experiments of Bequerel prove not only the fatal effects to warm-blooded animals of an entire suppression of the cutaneous functions, but that death is always preceded by a rapid and extreme fall of the animal temperature from the full blood-heat of the animal to within a few degrees of the temperature of the air. The reader may remember that, in conjunction with a colleague, he coated the surface of rabbits, after removing their hair, entirely over with an impervious plaster of substances, not in themselves injurious, but merely air-tight. The animals are stated to have died in a few hours, having in each case fallen greatly in temperature. As the air was about 60°, and the thick coating composed of materials which are not ready

conductors of heat, and as evaporation, the great cooling process at the skin, was entirely put a stop to, the loss of heat must have taken place chiefly from the pulmonary surface in respiration: and it proves how great that loss must be which can occasion such a fall of temperature, when any functions for the production of animal heat are disturbed. We may also gather from it evidence that a large portion, at least, of the heat is evolved while the blood is in the capillary vessels of the skin, and by a process nearly connected with its functions. Hence a suppression of these causes a great falling off in the supply of heat.

This extreme case may, I think, serve to explain many others where the same cause is acting in a minor degree. Some persons, to an extent that is almost paradoxical, appear to grow colder the more they wrap up, and especially in the feet. The distance from the centre of circulation may account for some portion of this; but where it is not relieved, but rather increased by thick coverings, some additional reason has to be found for this coldness of the extremities. As the outer covering of the feet is commonly of tanned leather, through which air can with difficulty enter to the skin, and vapour and gases make their escape from it, have we not a state produced verging towards that under the impermeable covering employed in Bequerel's experiments—namely, an increased tendency to coldness? May we not here find good reason for thinking that the development of heat in the part is checked by checking so much the action of the skin? Hence cloth boots may be warming, not only from their better confinement of the heat, but by their porous texture allowing of a more healthy play of the skin than tanned leather closely fitted to the member can permit. I have known persons who wore the modern waterproof boots, with the view of keeping the feet warm, find the sensation of oppression not compensated for by any additional warmth. But, on the contrary, the feet have been colder than ever. For such invalids I would be disposed to recommend the employment of tanned leather in their shoes, to be confined to the soles, and to a narrow edge rising not more than an inch, for keeping the feet dry; the whole of the

front, as well as the rest of the foot, being covered with cloth, instead of the part over the ankle only, as is common in cloth boots. In the same way we may, I think, find the whole surface oppressed, and yet sometimes rendered more chilly by the bulky clothing an invalid is compelled to wear, and with an adverse effect upon the lungs as its result. Compared with exposure to cold it may be the lesser of the two evils; but it is nevertheless proper to keep before our view the fact that it is trying to the system.

The employment of the modern India-rubber air-tight clothing, in the manner in which it is often used, would be noticed under a future head; but I may here remark, that all such covering, beyond a mere lappet, or very short cape for keeping rain from the shoulders, appears to me very undesirable, even for the healthiest persons. I entertain this opinion not only upon the usual ground of objection, and that a weighty one, the suppression of the perspiration, but because there seems much reason for thinking that it tends to enfeeble the production of animal heat over the whole surface; and therefore the important process also of which this is a part, namely, the separation of waste matter in the blood, in a form ready for elimination as soon as the blood comes round to the lungs. Among causes working gradually, one could hardly imagine any of a more deleterious character. That air-tight covering acts in this manner, in a greater or less degree, there is, I think, strong evidence for thinking. In proportion as they hang loosely on the body, the effect is no doubt moderated; but it is still pernicious of its kind.

Having afforded such attention as my space permits to the influence of the atmosphere, in causing or aggravating pulmonic symptoms by its direct action on the lungs, and to its indirect action on them in various ways, a few words have to be said upon the influence of impurities artificially introduced into the air. In so wide a question, with the particulars of which I shall presume the reader to be acquainted, I shall here confine myself to a few general observations. Passing over the manifestly deleterious properties of the gaseous impurities thrown into the air

in the processes of many of the arts, and by the crowding of human beings in confined and ill-ventilated spaces, as matter belonging to a future head, it is only necessary here to speak of the impurities drawn into the lungs in respiring the ordinary atmosphere of cities. Mr. Thackrah, in his work on the Employments of the Industrious Classes, to be admired for the careful observation, judgment, and benevolence, which it exhibits, appears to consider the general atmosphere of cities\* to conduce only to bronchial irritability, and not to other pulmonary diseases, but rather to lessen the advance of pulmonary consumption. In whatever degree the air of large cities may be warmer than that of the country, it may be so far less trying to lungs, but its impurities must, I conceive, greatly counterbalance any trifling difference of this kind. To such an extent as my own opportunities have reached, I have been led to view them as a serious evil; and I believe most physicians in the metropolis consider the air of London generally prejudicial in all stages of pulmonary disease.

Some time ago I visited the workshops of cutlers in Sheffield, with the hope of devising some efficient remedy for the well-known evil to which the grinders are subjected. There appeared to me no reason for doubting that the object might be attained, by improving the dust-sucking apparatus they employ, and by changing the position maintained by the body, for which purpose the grindstones would have to be set differently; but the indifference, not only of the employers I spoke to, but even of the employed, to the evil, caused me to give up the pursuit. Some of the men seemed to prefer the present advantage of the partial monopoly which the unhealthiness of the occupation tended to command! My inquiries led me to the conclusion, that no inconsiderable part of the effects on the lungs of the grinders arose from the habitually compressed state of the organ caused by the position of the body†. At the same time the cause

\* On Employments affecting Health and Longevity, 15.

† This appeared from the fact that some grindstones were provided with a blowing apparatus, which drew away the steel and stone dust, yet the effects to the workmen were only removed in

usually assigned, namely, the dust, was in most cases in full operation, and with consequences, as I learned from many workmen, of as direful a kind as is commonly reported. The evil has been attributed to the steel dust solely; but, although it has its share doubtless in the work, I have been inclined to think the dust from the stones themselves is the chief agent, since it is much greater in quantity and coarser than the steel dust, yet quite fine enough to be carried in with the breath; and as the action on the lungs is to be considered of a mechanical kind, the siliceous particles from the stones are more likely to retain their asperities and angles undissolved, and to cause more injury than even the iron of the steel. This opinion seems confirmed by a fact I learned, that fork-grinders are in an especial degree sufferers by their occupation. Now the irregular surfaces, and pointed extremities of a fork, will cause a stone to grind away with much more than proportional quickness to the wear of the broad and even stones, subjected to the equal pressure of knife blades.

The dust of cotton, wool, and flax, is well known to render certain branches of the manufactures connected with them also very injurious to the lungs, though in a less degree.

From these *extreme* effects of mechanical impurities in the air, we might be satisfied that the *smaller* proportion of particles in the ordinary atmosphere of cities would be trying, to a certain extent, to so delicate a membrane as that lining the air-passages. But we have daily evidence of the fact, especially in the metropolis, where so many acrimonious particles of smoke are also present.

To the urgent reasons for controlling by art the quantity of air respired by pulmonary invalids, we have here added the expediency of endeavouring to separate from it particles of solid matter by mechanical or other means.

---

part. In some cases this could be accounted for by the rude construction of the apparatus, and the carelessness of the men in using it. But in other instances I was satisfied that the removal of the dust was complete, and still the occupation was injurious, though in a less degree, even to those who were quite sober men. That this remaining effect was caused by the position, the workmen themselves were of opinion.

---

## HÆMORRHAGE FROM EXTRACTION OF TEETH.

*To the Editor of the Medical Gazette.*

SIR,

IN your number of April 1, a case of alarming hæmorrhage consequent upon the extraction of a tooth, is reported from a communication of Mr. Davenport, of Eltham.

A somewhat analogous case occurred under my own observation about three years since. The subject of it was a stout and healthy young man, who applied to me for the removal of a molar tooth from the lower jaw, which was effected without any difficulty. The following day, he presented himself, saying that the bleeding had continued the whole of the day and the succeeding night; and from his appearance there could be no doubt of his having lost a considerable quantity of blood. Various styptics were applied, and firm pressure was maintained by filling the cavity with lint soaked in tr. ferr. sesquichlorid., and placing over this a piece of cork, which was kept in close contact with the upper jaw by a bandage fastened over the head and underneath the chin.

These means, however, were insufficient to restrain the hæmorrhage, for on the third morning after extraction, on removing the lint and coagula from the socket, arterial blood issued forth, *per saltum*, into the mouth.

I now determined upon using the actual cautery; and for this purpose I procured a common knitting-needle, bent at its extremity for the length of an inch to a right angle, and having brought it to a red heat, I applied it to the bottom of the cavity.

The success of this measure was immediate and complete, and but little pain was caused by its application.

It is worthy of remark, that in this, as in Mr. Davenport's case, the hæmorrhage ensued upon extraction from the lower jaw; attributable, no doubt, to the larger size of the arteries in the lower than in the upper jaw.

I should not have troubled you with this communication, but Mr. Davenport having expressed a desire to be informed by your readers of any means more likely to be successful than those usually resorted to in such cases, I beg to suggest the above-described plan, which, from its having succeeded so

well in my own case, I can recommend as worthy of adoption when more ordinary means have been found unavailing.—I am, sir,

Your obedient servant,  
HENRY CHURCHILL, M.R.C.S.  
Stockwell Common, April 8, 1842.

#### ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

*The Elements of Materia Medica and Therapeutics.* By JONATHAN PEREIRA, M.D. F.R.S. and L.S.; Licentiate of the Royal College of Physicians in London; Member of the Royal College of Surgeons; &c. &c. 2 vols. 2d edition, enlarged and improved. London: Longman and Co. 1842.

FAVOURABLY as we thought of the first edition of this work, we did not expect that a second would have been so soon required, knowing that a large impression had been struck off. The sale, however, it would appear, has been more commensurate with the merit of the volumes than is sometimes the case, and we are glad to have Dr. Pereira once more before us. We find many improvements. A large number of woodcuts have been added, and numerous alterations for the better made in the typography. The processes in all the British Pharmacopœias have been described more fully, besides which additional articles are given on a variety of subjects connected with therapeutics: among which we may enumerate climate, diet, heat, light, electricity, magnetism, &c. &c.

We had no idea that the work admitted of being so much improved, and we heartily wish the learned author all the success which his zeal and activity so eminently deserve.

*A Dispensatory, or Commentary on the Pharmacopœias of Great Britain: comprising the Natural History, Description, Chemistry, Pharmacy, Actions, Uses, and Doses of the articles of the Materia Medica.* By ROBERT CHRISTISON, M.D., F.R.S.E.; Professor of Materia Medica in the University of Edinburgh. Edinburgh: Adam and Charles Black. London: Longman and Co. 1842.

THIS work, as the title implies, is not a mere commentary on the Edinburgh

Pharmacopœia, but a commentary, and a most instructive one, on the Pharmacopœias of the three capitals. The plan, too, is essentially different from that adopted by Dr. Duncan. The introductory treatise on pharmacy is omitted; and instead of being divided into different parts, as has hitherto been done in our various Dispensatories, each individual subject has been discussed under a single head: a short but complete treatise being given on each article of the materia medica. Great care has evidently been bestowed upon the physiological actions and therapeutic qualities of the drugs. It is a most valuable addition to our works upon Materia Medica and Pharmacy.

*Principles of Human Physiology, with their chief applications to Pathology, Hygiene, and Forensic Medicine, especially designed for the use of Students.* By WILLIAM CARPENTER, M.D.; Lecturer on Physiology in the Bristol Medical School. London: Churchill, 1842.

THE “Bristol Medical School” is fortunate in having such a lecturer as Dr. Carpenter, whose most elaborate and important work now lies before us. In the introduction we find the connexion of physiology with the other departments of medical science clearly pointed out, and the use it is of to pathology and treatment satisfactorily elucidated and explained. Another point forcibly alluded to is the bearing of statistics upon medicine—a circumstance of great importance to be kept in mind, and generally too much neglected.

Dr. Carpenter next proceeds, in his first chapter, to trace the rank occupied by our race in the scale of created beings, which gives him an opportunity of referring to the lower as well as the higher classes of the vegetable and animal worlds. The functions of the body occupy the second chapter, and they are all passed in general review before entering upon them in detail, as he afterwards proceeds to do. The nervous system, as a matter of course, occupies a large share of his attention; and he fully enters into the views of Sir Charles Bell and Dr. Marshall Hall.

All the most interesting points connected with digestion are made to oc-

occupy a chapter on that important subject, and the views both of the continental and American physiologists brought before us: in short, the most important facts connected with the nervous system, muscular fibre, organic functions, and reproduction, successively occupy his attention, and the subjects are elucidated by numerous, and some of them very beautiful, illustrations. We may add too, though last not least, that the student will find an excellent and comprehensive index. We have been anxious to bring this work as early as possible before our readers, not pretending to give them any of the information which it contains (for with respect to a volume of this nature to do this effectually would require several entire numbers of our journal), but merely pointing out to them the abundant fountain whence they may draw for themselves.

---

## MEDICAL GAZETTE.

Friday, April 15, 1842.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

---

## EMENDATIONS OF THE NEW POOR-LAW.

In our number of March 25, we commented on the remarkable inefficiency of the medical relief doled out to the poor under the provisions of the new Act. Many instances, besides those which we quoted, are to be found in the valuable pamphlet on the administration of medical relief to the poor, published by the Provincial Medical and Surgical Association.

Thus, in the Shipston-upon Stour Union, the Guardians entrusted one medical officer with three districts, which "contained 30 parishes, 15,000 inhabitants, and extended 15 miles by 14; the greatest distance from the medical officer being 10 or 12 miles."

The next year they gave him *the whole Union*, containing a population of 19,030.

The third year they deprived him of one of the four districts; and in the fourth year they were obliged to appoint a separate practitioner to each of the four divisions. We may imagine what a stormy height the complaints of inefficiency must have reached, when the Board was obliged to deviate into common sense, and make it less impossible for the indigent poor to obtain advice, though at an increased charge of several pounds per annum!

The Wheatenhurst Union, with a population of 7770, might have enjoyed the services of two established practitioners for 150 guineas a year, and £1 per case of midwifery. The Assistant-Commissioner thought this too high; fixed the salary at £100, and the reward of midwifery at ten shillings the case; and made the Board advertise.

"One reply was received from a perfect stranger, accepting the offer; and he was appointed to the care of the whole Union, extending, in its longest diameter, 14 miles. His place of residence was determined by the Board. He actually undertook his duties without a horse, or even a catheter."

The unfortunate surgeon soon wished to resign, but this was not in the bond. The Shylocks of Wheatenhurst were determined to have their pound of flesh; indeed, if the stranger continued to perform his duties without a horse, they must have obtained a good many, for walk round the 14 parishes of this Union would be wonderfully attenuating. At the end of his year, of course, he departed: his successor had more fortitude, and remained two. And thus ends the history of the Wheatenhurst Union in the pamphlet: we should like to see its continuation.

In the Crickhowell Union, a young man, who did not understand a word of Welsh, was appointed to one half of the Union, "where you may go for miles before you could meet with a

person who could interpret between the medical man and his patient." In a case mentioned by Dr. Yelloly, unjust economy seems to have reached the limits where folly borders on insanity.

"A large parish in West Ham Union, containing 4000 inhabitants, was previously provided with drugs at the expense of the parish, a dispenser engaged at a small salary to make them up, and attendance on the patients given by the resident surgeon gratuitously; but yet, though the expense of the drugs alone amounted to near £70 per annum, the Guardians felt themselves justified in contracting for drugs and attendance together, at £50 per annum!"

How distorted must be the views of those who can allow the work to be performed for so inadequate a sum; how unenviable must be the condition of the profession, when qualified persons can be found to undertake the task! Mr. Farr has shown that, on the average of several counties, the rate of remuneration is 3s. 3½d. per case; while in English jails it is 13s. 7d., and in Irish ones still higher.

Mr. Farr's explanation of this difference appears to be correct. The consequences of neglecting the health of prisoners are so glaring, that they cannot escape observation. The report of a jail fever carrying off a score of victims excites both alarm and indignation; while deaths from neglect in a scattered district make no general impression.

We may add, however, that the enormous abuses interwoven with the new system have been practised on so great a scale, and persevered in with so much hardihood, that they have at length roused public attention; and though the victims of medical relief have not yet found their Howard, the efforts of philanthropists have been crowned with a certain degree of success. Our readers will have observed

from Mr. Guthrie's letter, and the papers of the Poor-Law Commissioners, inserted in our number for March 25th, that some of the more prominent iniquities stand a good chance of being moderated. We have not killed the snake, but we have scotched it.

Mr. Guthrie's letter contains a good abstract of the mitigated code, with a favourable commentary upon it. In the first place, the system of tender is abolished, in so far as it is a system of underbidding. The Board of Guardians will fix the sum for a district, and though various practitioners may offer to fill the place, the Board is to pay the sum fixed in its own original notice; so that the contest will turn on the respective merits of the practitioners, and not on their readiness to undersell each other. We shall rarely hear, after this, of the threat of bringing down "talented young men from London" to lower still farther the slender gains of the country practitioner. The appointments, too, are to be permanent, not yearly—another great improvement. The medical officers to be appointed in future must hold one of four different qualifications, enumerated by the Commissioners. The first three consist of the diploma of the London College of Surgeons, together with

(a.) An English medical degree, or license from the Royal College of Physicians of London; or,

(b.) A license from the Society of Apothecaries; or,

(c.) Actual practice as an apothecary on August 1, 1815.

In all these instances, it will be observed that a double qualification is required; in the fourth, only one is mentioned, namely, a warrant as surgeon (or assistant-surgeon) in the army, navy, or East India Company's service, or as apothecary in the army, provided the warrant is dated before August the 1st, 1826. We presume that in all

these instances the candidate examined by the public board was already a member of the College or Hall, so that this fourth qualification is likewise a double one.

The Commissioners, in their commentary, observe, that they have limited their qualifications to those proceeding from an English source; but if a practitioner possesses an English qualification as physician or apothecary, and a surgical one from Ireland or Scotland, they will allow him to be elected, on application from the Guardians, for that purpose. This seems right; for the medical barriers set up between different parts of the empire are usually too unyielding; so that medical practitioners and ardent spirits are among the articles which most forcibly remind us that these islands were once divided into three separate kingdoms.

The principal operations of surgery are to be paid for extra, provided the operator has obtained what Mr. Guthrie calls a "consultation certificate;" that is, a certificate that the amputation or trephining was necessary, from a member of the College of Surgeons or Physicians. It does not appear that this certificate is required for the operation for strangulated hernia. The remuneration is fixed in a schedule given by the Commissioners. The fee for a labour is to vary from ten shillings to two pounds, according to circumstances. Mr. Guthrie believes that the fee is to be a pound when the distance of the patient from the surgeon, in an ordinary labour, exceeds two miles.

The maximum area and population of a district to be allotted to any one medical officer are fixed; the former at 15,000 acres, the latter at 15,000 inhabitants. We entirely agree with Mr. Guthrie in thinking both these quantities too large by one half. He is of opinion that no Union surgeon should

be made to go more than three miles from his own door, if possible.

Mr. Guthrie makes some judicious observations on the necessity of a general principle being established for the remuneration of Union surgeons. As no such principle is acted on generally, by Boards of Guardians, the practitioner, whose wants compel him to take whatever they may think proper to offer, is often paid only a half or a third of what he ought to receive, even according to the economical computations contained in the reports of the Assistant-Commissioners. When a man is paid so ridiculously little for his services, what follows? Take the answer in the plain words of Mr. Guthrie:—"They are, therefore, not performed, and the poor have only the semblance of medical assistance, but not the reality, in many parts of the kingdom; and they never will have it until a principle of remuneration for medical services shall be laid down, and enforced by the Poor-Law Commissioners."

Wherever there is a workhouse, says Mr. Guthrie, it should be paid for separately, at the rate of ten pounds per annum for every fifty persons, and seven pounds for drugs for the same number. It must be confessed that this recommendation (whoever may have devised it) does not err on the side of extravagance. Ninepence for the daily visit will not startle the most economic Board, or stimulate it into advertising for a cheaper man.

Two other articles in the new regulations, both worthy of approbation, remain to be noticed. By one it is ordered that every Union surgeon is to give into the Board of Guardians the name of some qualified practitioner, to whom application may be made, in case of his own absence from home. By the other, Boards of Guardians are directed to give tickets every six months to permanently sick or disabled persons, en-

titling them to medical aid without any order from the relieving officer.

In a word, these new regulations are good, as far as they go; they are a series of victories gained by good feeling and good sense over the harsh Malthusianism which has stamped the working of the New Act. May the press still continue to advocate the cause of humanity, and may we have reason to say to the Poor-Law Commissioners—

*Lenior et melior fit accedente senectâ !*

#### UNIVERSITY OF LONDON.

WE cannot but regard the course which the Senate of that institution has lately been pursuing, as betraying a strange vacillation and inconsistency of purpose, and as being calculated seriously to injure its character and impair its utility. It would appear that in the beginning of the present winter\* the Chancellor of the Exchequer issued a recommendation to the Senate to revise their estimate of expenditure, with a view more particularly to a reduction in the amount of salaries, on the pretext that the late House of Commons had condemned that expenditure as being excessive. The reply of the Senate, adopted after full and mature deliberation,† was, that "They are not prepared to recommend any reduction in the estimate, and fear that a diminution in the inducements which they have it in their power to offer to candidates for the office of examiners might be attended with injury to the institution." On receiving this reply, the Chancellor of the Exchequer informed them‡ that he would, of his own authority, make a reduction of £800 in that portion of the grant which regards the salaries. The announcement of this sudden curtailment of their resources induced the senate at once to abandon their former position; thus pleading guilty to the charge so often made against them by their adversaries, both in and out of Parliament, of having abused their powers by bestowing on their principal examiners salaries

very disproportioned to the amount and to the importance of the duties they performed. Their eyes appeared on a sudden to be opened to the new light which dawned upon them, and they set about effecting a complete alteration in the former scale of salaries. The largest reduction has been made in the salaries of the examiners in the principal branches of medicine; and in one department, that of physiology and comparative anatomy, in which the choice of men of eminence is still more limited, they have cut down the salary of the examiner almost to one-third of that which they had hitherto assigned to it, while they have reduced only to a very small extent those of the examiners in classics and mathematics, to fill whose offices it is much more easy to find a great number of candidates of competent abilities. The only course which the Senate could have pursued, consistently with the opinion they had so recently expressed to the Chancellor of the Exchequer, that the scale of salaries originally established was the best for the purposes of the University, was to make an equable reduction in all the salaries, so as to preserve among them the same relative proportion as at first. Instead of this, while they have diminished the salaries of the examiners in classics and in mathematics from £200 to £175, they have reduced those of the examiners in anatomy, in surgery, and in medicine, from £250 to £175, and that of the examiner in physiology and comparative anatomy from £250 to £100. It is unnecessary to point out to those who form a just appreciation of the value of these fundamental branches of medical education, to what extent such a disparagement of these essential studies will operate in injuring the character of the medical degrees conferred by this University.

We have heard that the resolution, by which the importance of physiology and comparative anatomy has been so strangely depreciated, was passed at a very small meeting, without previous notice; and the measure, thus precipitately carried, was acted upon so promptly as to allow no opportunity of remonstrance from the other members, no doubt composing a large majority of the Senate, who disapprove of the measure. Its necessary consequence has been the retirement of the exa-

\* Letter of Mr. Goulburn, Nov. 25th, 1841.

† Dec. 8, 1841.

‡ Dec. 23, 1841.

miner, whose office has been thus so preposterously lowered from the rank hitherto assigned it. The following letter from Dr. Roget, to the Registrar of the University, expresses the reasons he gives for thus retiring:—

Bernard Street, Russell Square,  
Feb. 19th, 1842.

Sir,—In answer to the request of the Senate, that I would inform you whether I am willing to continue my services as examiner in the ensuing year, I beg you will state to them that the new scale of salaries which the Senate have adopted is so different from that to which they have long adhered, which was so entirely approved by the Government, and which the Senate had so recently determined ought to remain unaltered; and especially as, in that new arrangement, the importance of the examinations in physiology and comparative anatomy is placed so far below that of the other branches of medical study, to which that department had hitherto, from the first, been considered by the Senate as being of equal importance; and as my own opinion remains unchanged with respect to the estimation in which a knowledge of physiology and comparative anatomy ought to be held as a qualification for our medical degrees, I consider that the same services as those which I have hitherto been happy to render the University as examiner in these branches, are no longer desired, and I accordingly decline to tender them. If, at some future period, the views of the Senate in this respect should again be altered, I shall ever be ready to renew those exertions to promote the objects of the University.

I am, sir,

Your obedient servant,  
P. M. ROGET.

R. W. Rothman, Esq., &c. &c.

#### COLLEGE OF PHYSICIANS.

SENIOR AND JUNIOR FELLOWS.

*To the Editor of the Medical Gazette.*

SIR,

In your number for April 8, 1842, which has just reached me, under the head "Proposed Changes in the College of Physicians," it is stated, "that all who enter the College are to become 'Members;' by whom and from among whom the Fellows are to be chosen. This is the kind of change we have often advocated in the MEDICAL GAZETTE; embracing, as it does, the abolition of the obnoxious appellation of "Licentiate,"

and giving to all certain rights and privileges as *bona fide* Members of the Corporation."

Now, sir, I have for long been of opinion that the Members of the College should be divided into two classes, under the designation of Senior Fellows, and Junior Fellows: thus not only would the obnoxious appellation of "Licentiate" be done away with, but also the equivocal and hardly less obnoxious appellation of "Member;" a name which has for many years been assumed by the Licentiates—as the titles of numerous medical works can testify.

For the appellations I propose, there is at least an excellent precedent in the division of the Fellows of some of the Colleges at Cambridge into senior and junior; as, for example, at St. John's, Trinity, and King's College.—I remain, sir,

Your obedient servant,

A PHYSICIAN.

April 1842.

#### ARRESTING OF HÆMORRHAGE.

*To the Editor of the Medical Gazette.*

SIR,

YOUR correspondent, Mr. Davenport, wishes to be informed of some remedy for the suppression of bleeding after the extraction of a tooth. I beg leave to say that, during a practice of thirty years, I have had several cases of continued bleeding after the extraction of teeth, and have always succeeded in arresting the hæmorrhage by plugging up the socket with a soft cork, nicely shaped, and previously dipped in the undiluted sulphuric acid; and in no one instance have I had to repeat the application.

I am, sir,

Your obedient servant,

THOMAS SILVESTER.

West Bromwich, Staffordshire,  
April 12, 1842.

*To the Editor of the Medical Gazette.*

SIR,

IN cases of serious and alarming hæmorrhage, arising from apparently trivial causes (as in Mr. Davenport's case subsequent to the extraction of a molar tooth, reported in the GAZETTE of April 1st), I imagine that we should experience much less difficulty in restraining it if general treatment was employed as well as local. From what I can learn, these cases occur generally in those persons who are prone to the hæmorrhagiæ. Why not treat them, therefore, upon the same principles as the nosological hæmorrhages? Some cases might warrant the employment of the lancet, administration of the potassio-tartrate of antimony, saline aperients, &c.; others would require acetate of lead, with opium and acetic acid; sulphuric acid, with

or without quinine; sesquichloride of iron, &c.—as the discriminating practitioner might deem best adapted.

Of local means in restraining hæmorrhage from alveolar cavities, pressure is, undoubtedly, the best, and most successful, when the continuance of the pressure is superintended by the medical attendant. Patients are not of themselves sufficiently persevering, but too anxious or curious to ascertain whether the means are or are not successful. The cavity might be filled with pounded ice, or cold water applied to the head by means of shower bath, with advantage.

Should the above suggestions be deemed worthy a corner of the *MEDICAL GAZETTE*, their insertion would much oblige

Your obedient servant,  
E. R.

April 5, 1842.

*To the Editor of the Medical Gazette.*

SIR,

HAVING read, in some late numbers of your very excellent medical journal, an account of two cases of hæmorrhage after the extraction of a tooth, one of which unfortunately proved fatal, from its being complicated with a hæmorrhagic diathesis; and the other nearly so, or at least to that extent to demand a consultation, I beg to forward a short description of that which I consider to be the most effectual plan of any that I have ever heard, or read of, for suppressing this most troublesome and dangerous bleeding. In fact there are few cases, if any, of this interesting kind of hæmorrhage that may not be restrained by the following means.

Take a cork, of sufficient length, and of the exact size of the tooth extracted, out of which cut a V, or triangular-shaped piece, and place it over the parts from whence the bleeding proceeds, having previously filled the dental cavity with a small, yet firm, pledget of lint, dipped in the muriated tincture of iron; and if, after this, the hæmorrhage is not controlled, depend upon it it is owing to the abuse, and not the use, of the means above mentioned; for its advantages over any other extant are so evident, that no one can for a moment doubt the certainty with which it acts. The ergot of rye, in a case where there is anything of a hæmorrhagic diathesis suspected, should be given to its fullest extent, for reasons which I will give, with your permission, in a future communication upon the properties of this drug.

I am, sir,

Your obedient servant,  
JEPHTHA HUSSEY,  
M.R.C.S.L.

Liverpool, April 12, 1842.

P.S.—It is unnecessary almost to add that pressure by closing the tooth is requisite in using the cork, as stated above.—J. R.

## CLINICAL LECTURE

ON

### DIABETES MELLITUS,

*Delivered at King's College Hospital,  
Jan. 12, 1842,*

By GEORGE BUDD, M.D., F.R.S.,  
Professor of Medicine.

GENTLEMEN,—Diabetes mellitus—the disease I have chosen as the subject of my remarks to-day—has always seemed to me of especial interest, not only from the remarkable fact—a fact fit to command the attention of the most indifferent—that the urine in this disease contains habitually a large quantity of sugar; but also from its showing, by an extreme case, the great importance of studying urinary disorders, and from its displaying the kind and degree of insight into pathology, which chemistry is likely to give us. You have had abundant opportunity of making yourselves familiar with its ordinary symptoms, in the case of Joseph Hawkesworth, who has been in the hospital under my care since the 8th of October.

He is a painter and glazier, 37 years of age, of middle stature, and square athletic form; and has always resided in Greenwich.

His habits have been very temperate; and he had no illness that he can recollect until 13 years ago, when he was laid up six months by an attack of rheumatic fever. He recovered perfectly, and again enjoyed good health, and was a strong, robust man, until the summer of 1840, when he had painter's colic, which lasted, off and on, for two months. From this time his health was again good, until the beginning of last September (about a month before his admission to the hospital), when he became thirsty, and his mouth and tongue hot. He had also great craving for victuals. About the same time he remarked that he made a greater quantity of water than he

751.—xxx.

used to do, and that he was obliged to get out many times in the night to pass it. These symptoms continued, and he lost flesh and strength.

When he was brought under our notice his limbs were still tolerably muscular; his complexion was of a peculiar sallow, or straw colour; his skin harsh, dry, and wrinkled; his tongue, moist, and covered with a thick, yellowish brown, pasty coat. He had a very craving appetite, and much thirst; and passed daily about 10 pints of urine, which was slightly acid, very transparent, and free from sediment, of a light amber colour, and of sp. gr. 1035. His bowels were costive, and he complained of a sensation of coldness across the belly, with occasional aching pains there. He had no pain or apparent ailment any where else, was free from fever, and slept well.

At this time he offered a type of uncomplicated diabetes. The disease generally commences obscurely, and in most cases the first symptom that attracts the patient's attention is inordinate secretion of urine, and frequent desire to pass it. The urine is always of a pale straw colour, and generally very transparent. It has often been remarked to have a peculiar faint smell, which has been compared to that of sweet hay or milk; but our senses are not fine enough to detect any such peculiarity in the urine of Hawkesworth. The quantity of urine passed daily is always very much above the natural standard. Instead of 35 or 40 ounces, which is about the average of health, the patient, before he has been put under treatment, generally passes as much as 10 or 12 pints, and occasionally twice or even three times as much.

The urine is not only increased in quantity, but, contrary to what happens in healthy states of the system, in which increase in quantity is compensated by diminution of density, it is increased in density also. Instead of falling within 1010 and 1030, which are, probably, the limits of

M

health, the sp. gr. usually ranges between 1035 and 1045; and in some instances it attains the extraordinary height of 1055.

From increase in the quantity of urine, and likewise in its density, we might, of course, infer that there is augmentation of the amount of solid matter discharged.

The average daily discharge of solids by the urine, in a person well nourished and in a high state of health and vigour, has been estimated by Dr. Christison at two and a half ounces, of which nearly one half is urea.

On the 11th of October, three days after his admission to the hospital, Hawkesworth passed, in the course of 24 hours, 10 imperial pints of urine, of sp. gr. 1040. In his chapter on diabetes, Dr. Prout has inserted a table, constructed by the late Dr. Henry, showing the quantity of solid extract obtained by evaporating a wine-pint, or 16 ounces of urine, for every degree of density from 1020 to 1050. Calculating from this table, it appears that Hawkesworth passed, on the day in question, nearly 20 ounces, or more than a pound and a half, of solid matter, in his urine.

We arrive, then, very readily at the fact, that, in diabetes, a large quantity of liquid and of solids passes off from the system as urine. Another fundamental fact in the pathology of diabetes, is, that the chief part of the solid matter of the urine—in fact, almost all the excess above the natural quantity of solids—consists of sugar, which resembles in its properties the *low* sugar of grapes.

It was at one time supposed that urea was entirely wanting in diabetic urine; but this opinion has lately been shown to be incorrect. Mr. Macgregor, Dr. Christison, and M. Bouchardat, have not only succeeded in obtaining urea from diabetic urine, but they seem to have established that the quantity of this principle passed daily is more frequently above the healthy standard than below it; a fact which is connected with the highly animalised regimen, which is a fundamental part of the treatment of diabetes. According to M. Bouchardat, the quantity of urea, as in health, is proportioned to the quantity of azotised food which the patient consumes.

Free lactic acid and lithic acid are also found in diabetic urine, together with the ordinary saline ingredients, which, according to Dr. Prout, are nearly in the same relative proportions as in health.

It would seem, then, as stated by Dr. Christison, that, except in advanced stages of the disease, or when, as sometimes happens, this is complicated by granular degeneration of the kidneys, the urine may be considered healthy urine with the addition of so much sugar.

It was at one time supposed that the

sugar found in the urine in diabetes was produced by disordered action of the kidneys; but this supposition has been lately disproved by the interesting discovery that sugar exists in the blood likewise. Many physicians have, indeed, failed to discover sugar in the blood of diabetic persons; but its existence in that fluid, which was maintained in the last century by Dr. Rollo, was ascertained, three or four years ago, by Dr. Maitland, who succeeded in obtaining crystals of pure sugar from the blood of a diabetic patient. Since that time sugar has been found in the blood of persons affected with diabetes, by Mr. Macgregor, Dr. Christison, M. Bouchardat, and others.

In some cases, however, the quantity of sugar found in the blood has been extremely small. It would appear, from some analyses made by M. Bouchardat, that this quantity varies with the time at which the blood is drawn, and that it is greatest in blood taken soon after the act of digestion.

And this naturally leads me to another fact recently discovered, which, by tracing the evil to its source, completes the chain of evidence by which chemistry has thrown so much light on the pathology of diabetes. I speak now of the discovery that in diabetic persons sugar is formed in abundance in the stomach by the process of digestion, and that it may be detected by fermentation or crystallization, in matters vomited after digestion has commenced. This most interesting discovery was first made by Mr. Macgregor, and has since been confirmed by Bouchardat. It is clear, therefore, since the sugar is formed in the stomach, that the blood must be the channel through which it finds its way into the urine. From the fact, that the quantity of sugar found in the blood of diabetic patients is often small, we must not conclude that all the sugar in the urine has not existed, as sugar, in the blood. The reason why a small quantity only is found is, that it passes off very readily by the kidneys, and, consequently, cannot accumulate in the blood; and that the quantity actually present in that fluid is diffused through its whole mass. The same thing happens for many other agents, which find their way to the kidneys through the same channel. The urine of animals poisoned with arsenic or antimony soon becomes much loaded with these substances; but, nevertheless, if the subject of experiment survive this period for a few hours, it often happens that not a particle of the poison can be detected in its blood. This was ascertained, over and over again, by M. Orfila, in his interesting series of researches on the action, and mode of detection, of these poisons.

Urea offers another case in point. A large quantity of this principle exists naturally in the urine, while its presence in the

blood of a healthy person can scarcely be detected. But, notwithstanding this, it is well established, that urea is not *formed* by the act of secretion, but that the whole amount of it found in the urine exists previously, as urea, in the blood. Passing off in the urine as fast as it is produced, no accumulation takes place, so that little can be found in the blood at any one time. It is quite clear from these considerations, that the sugar in diabetic urine is not formed by the kidneys, but merely eliminated by them; and since this urine contains no other morbid principle, and since the other solid ingredients are in nearly the same proportions as in health, that diabetes can in nowise be considered a disease of the kidneys.

This view is confirmed by anatomy. The kidneys of persons who have died of diabetes are occasionally found somewhat congested; but they exhibit no appearances that might serve to characterize the disease. In some instances they are perfectly healthy. In a patient of mine, who died in the hospital last year of this disease, they were examined under the microscope by Mr. Bowman; but, notwithstanding his familiarity with the microscopic characters of the organ, he could detect no deviation whatever from its natural texture.

The evidence, then, seems complete, that, in diabetes, sugar is formed in the stomach from all substances capable of being readily converted into it—that the sugar so formed is absorbed into the blood—and that from the blood it passes off in the urine, and, perhaps, in other secretions. The quantity of sugar formed in the stomach is, as might have been anticipated, very much increased by a vegetable diet. It has been long known that, under such a diet, the quantity of sugar in the urine is much increased, and all the symptoms of diabetes are much aggravated; and, on the other hand, that by restricting the patient to a diet consisting exclusively of animal food, or of aliments not easily convertible into sugar, the quantity of sugar in the urine is immediately reduced, and the progress of the disease stayed.

We are now in a condition to explain many of the most striking symptoms of the disease.

The conversion of a large portion of the food into sugar, which is not assimilated, but passes off from the body again in the excretions, explains both the craving for solid food, and the fact that, when the inordinate appetite is freely indulged, the patient still loses flesh and strength.

When Hawkesworth was first admitted, he was passing, as I have shown you, more than a pound and a half of solids daily in his urine; and nearly the whole of this must have been sugar. In him, therefore, nearly a pound and a half of his best food was daily

converted into this substance. Perhaps quite as much as this, for it has been ascertained that a considerable quantity of sugar is discharged from the bowels, and there can be no doubt that some portion escapes from other surfaces. Now all the food so converted is lost for nourishment, and we must make abstraction of it in estimating the quantity of aliment the patient takes. He is in the condition of a man whom necessity compels to live on food of the most innutritious kind, and who is obliged to make up for its defective quality by increase of quantity.

The great quantity of urine voided in diabetes—in other words, the great drain of liquids from the system—offers a still more obvious explanation of the thirst, the clammy mouth, and the dry skin.

All the symptoms I have mentioned—the craving for food, the loss of flesh, the thirst—are in evident relation with the density and amount of the urine; that is, with the loss of solids and liquids through this channel. Whenever by the influence of treatment, or otherwise, this loss is diminished, hunger and thirst diminish likewise, and the emaciation, if not entirely stayed, is rendered much less rapid.

The question now arises, what is it that determines the excessive secretion of urine? I believe it more than probable that the passage of sugar through the kidneys is its exciting cause. Almost all medicines which pass off largely by the kidney also cause free diuresis; and it is, as I believe, to the fact of their being eliminated through this organ that they owe their diuretic power. The same is true of the sugar in diabetes. It is no objection to this that sugar, as we usually take it, is not a diuretic, because in that case it is digested, and its qualities are completely altered, by the healthy stomach. It would be interesting to ascertain whether sugar injected into the blood would not increase the flow of urine.

It might, however, be supposed that the diuresis is owing to the large quantity of liquid the patient takes—that the disorder of digestion causes thirst—that the thirst leads him to drink largely—and that the diuresis merely results from the draining off of the superfluous water from the blood. If this were the order of causation, the thirst should be greatest soon after meals, and least in the morning before the night's fast is broken, and when the stomach has been for some hours empty. But, at present, Hawkesworth tells us, that he suffers most from thirst in the morning before breakfast, that he suffers little from it during the day, and not at all after his principal meals.

The thirst, then, is greatest, when he has been many hours without food, and after the kidneys have been a whole night draining liquids from the system. From this, and

from the dry state of the surface, and from the constipation so general in diabetes, coupled with the fact that we have a real, and very probably a powerful, cause of diuresis in the passage of so much sugar through the kidneys, we may infer almost with certainty, that the thirst is owing, as I have before stated, to the loss of liquids, and that the great consumption of these should be regarded as the consequence of the diuresis, not as its cause.

It has been remarked by several writers that the quantity of urine voided may very much exceed the whole amount of liquid taken by the patient; and an attempt has been made to explain this by supposing that fluid is then absorbed from the air by the lungs and skin. In cases in which the excess above the liquids allowed is great, and cannot be accounted for by the progressive emaciation, it is, I think, more probable that the medical man has been deceived by the patient; but if the fact should be established by future observations it would only confirm the inference, that the diuresis is the primary cause of the craving for liquids.

It, then, it be granted, that the diuresis is owing to the presence of sugar in the blood, or rather to its passage through the kidneys, it follows, that all the characteristic symptoms of diabetes may be traced to the production of sugar from the food, and its absorption into the blood. By this, a large proportion of the food is converted into a substance, which is not assimilated, and is, therefore, lost for nourishment; and an agent (sugar) is introduced into the blood, which is, probably, injurious by its presence there, and which, by its elimination through the kidney, causes diuresis, and consequently great drain from the body.

The formation of sugar in the process of digestion, and the absorption of this sugar into the blood, are, therefore, cardinal facts in the pathology of diabetes; and to explain these must be the prime object of all theories of the disease. Let us now see with what success this object has been fulfilled by writers on the subject.

According to Dr. Prout, who is justly regarded as high authority in these matters, diabetes may be said to originate in loss of the power to assimilate the saccharine principles we take as food.

Under the term "saccharine principles" are included sugar itself, and a large class of substances, which, from being easily convertible into sugar, and almost identical with it in chemical composition, may be regarded as its equivalents. These are mostly derived from the vegetable kingdom. The chief of them, considered as aliments, are woody fibre (the bran of corn, and fibres of other vegetables), gum, and starch; but the most important of these is starch.

In a state of health, all these forms of

vegetable matter, which constitute a large proportion of our daily food, are capable of being digested and assimilated; that is, of being converted into the constituents of blood, and thence into the several tissues of which our bodies are made up.

Now, according to Dr. Prout, they are all, in *healthy* digestion, first reduced to a *low* sugar; but this is only a transition state, and the sugar thus formed is at once converted into albuminous and oleaginous principles. Its existence in the stomach being, according to this theory, only intermediate and momentary, cannot readily be made a matter of experimental demonstration.

The first step, therefore, in the derangements in diabetes, consists, according to this writer, not in the formation of sugar in the stomach, which he considers a *healthy* process; but in the loss of that power which should convert the sugar so formed into the constituent principles of the blood, and through them into the living tissues of the body. He further believes, that, in advanced stages of the disease, sugar is not only formed in the stomach by the process of digestion, but that it is generated in other parts of the body from deranged assimilation, especially of the gelatinous tissues.

He considers the disease, then, to consist essentially in impairment or loss of this converting or organizing function of the assimilating organs.

But this is not the only theory that has been advanced to explain the phenomena of diabetes. It is found that in this disease the natural acid secretions of the skin are stopped; and that those of the mouth, as I have often pointed out to you in the case of Hawkesworth, are acid instead of being alkaline, as is usual in health.

Impressed with these facts, M. Bouchardat supposes that the disorder originates in suppressed perspiration; and that the acids which usually pass off by the skin escape by the mucous membrane and glands of the digestive apparatus; not that these acids have the power to convert starch into sugar at the temperature of the human body, but, he argues, wherever in organized beings they are found in considerable quantity, they are associated with diastase, or some analogous modification of albumen, which has this power. In illustration of this he brings forward the instance of unripe fruits, in which, as you know, these principles are associated to fulfil this object.

According to these views, diabetes originates in suppressed perspiration, and vicarious secretion of acid from the mucous membranes and glands of the digestive apparatus.

This theory is obviously too exclusively chemical. It seems to recognize nothing but chemical agency in the processes of the

living body. If it were true, we should expect that free sweating would at once arrest the disorder; but I need not tell you, after what you have seen in Hawkesworth, how far this is from being the case. Besides, the organic acids, to which M. Bouchardat ascribes all the phenomena of diabetes, are always in the healthy stomach, and sometimes in great excess, without giving rise to any symptoms like those of diabetes.

M. Bouchardat is, no doubt, right in the opinion, that the conversion of starch into sugar is effected by the chemical agency of secretions from the digestive organs. You have already seen that this change does take place in the stomach; and when you reflect that it is a purely chemical one, and very readily produced under a great variety of conditions, you will admit that the inference is unavoidable. At an appropriate temperature starch is converted into sugar both by acids and alkalis; and the same transformation takes place in several of the organic processes of plants, as in the ripening of fruits, and in the process of germination. The art of malting is, as you know, founded on this latter circumstance. And I beg you to remark that, although the functions of life are at this time active in the plant, yet this conversion of starch into sugar is a purely chemical matter, and quite independent of vital agencies. The proof of this is, that it goes on equally well when the materials of it are separated from the grain and mixed in their chemical form. The substance named diastase may be easily extracted from malt; and if it be then added in sufficient quantity to starch, all the starch is converted into sugar. Diastase is, as you know, one of the albuminous principles of plants, and, excepting this influence on starch, has no active chemical properties.

Since, then, the conversion of starch into sugar is such an easy matter, and especially since it is so readily effected in the tissues of organized beings, its accomplishment, by the chemical agency of the secretions of the stomach, is not difficult to conceive. But the mere conversion of starch into sugar does not explain diabetes; for a healthy stomach is capable of digesting large quantities of sugar. The blacks in the West Indies sometimes almost live upon sugar; but they do not get diabetes. What we have to explain is, not the conversion of starch into sugar, which there is reason to believe takes place in the healthy stomach\*, but the fact

that the sugar so formed is not digested and assimilated. To explain this we must admit some loss of power; and we are thus driven back on the theory of Prout. If, indeed, we should go a step further, and grant that the subsequent changes in the process of digestion, are, like the conversion of starch into sugar, effected by purely chemical agency of the secretions of the stomach, we have no reason to believe that a slight excess of the organic acids would prevent these changes; because, as I just now remarked, these acids are often in great excess in persons in whom digestion is not thus arrested, and who present no symptoms of diabetes. The alteration of the secretions of the stomach must be different from mere excess of lactic acid; and since this presumed alteration is *permanent*, we are forced, in order to explain it, to admit some organic change, or some modification of vital agency—as I just now expressed it, some loss of power.

I should not have thought it worth while to have alluded to this theory of M. Bouchardat, had it not been for the ingenuity which the author has displayed in his essays on this subject, and the idea that the theory may prove attractive to some from its apparent simplicity. At the present time, when organic chemistry is making great advances, there seems to be some danger that men of enthusiastic tempers will be led away, and fancy that chemistry is all-sufficient to explain the phenomena of life—that, as has been advanced by a distinguished French chemist, man, like a steam engine, is an apparatus that owes all its activity and all its power to the combustion of carbon. No one can be more sanguine than myself as to the results that may be expected from a study of organic chemistry. There can be no doubt that far more of the processes of the living body than has hitherto been supposed, are effected by mechanical or chemical agencies; but now, as much as ever, if we investigate those processes deeply, if we trace the phenomena backwards, we soon arrive at actions or changes, which neither chemistry nor mechanics can explain, and which force us to admit a vital agency distinct from either.

In almost all diseases, the two grand elements we are thus forced to recognize—chemical agency and living properties—largely enter: variously preponderating in their influence in different diseases. The part of the former precisely defined in some; in others, only obscurely recognized; but its importance not the less certain. Both most material to consider in our theory of disease, and both introducing their several indications into the treatment of the case.

\* Saliva, at the temperature of the body, converts starch into sugar. About half a pint of saliva was collected by Dr. Budd from a patient in King's College Hospital, affected with mercurial salivation. Some starch was then added to the saliva, and the mixture kept at blood-heat for an hour by means of a sand bath. A small quantity of yeast was then added; and on the temperature being maintained for an hour longer

rapid fermentation ensued; the mixture acquired the odour of new beer, and its surface became covered with a thick scum or froth.

It is from placing the importance of both these elements before us in a striking point of view, and distinctly defined in their separate influence and requirements, that diabetes is such an instructive lesson.

In the treatment of diabetes, according to the view I have taken of the pathology of the disease, we have two objects to aim at. The first and highest is, to strengthen the digestive and assimilating functions, in the impairment of which the disease seems essentially to consist; the second, to prevent, as far as possible, as long as the depraved digestion continues, the formation of sugar in the stomach, which, as I have already explained to you, seems to be the source of most of the other evils.

Unfortunately, we have as yet done little towards the attainment of the first object. Freedom from the harassing cares of business, and change of air, especially where the patient has resided in an unhealthy or malarious district, should be enjoined at the commencement of the disease, whenever the circumstances of the patient render such measures practicable. These ends would, perhaps, be best answered by a short sea-voyage, which I should also be disposed to recommend for other reasons, which I shall presently give you.

Beyond what can be effected by measures such as these, and by other obvious hygienic rules, we have little power to restore the digestive functions to their healthy condition.

In our endeavours to accomplish the second object—namely, to prevent the formation of sugar in the stomach—we are far more successful. We cannot, indeed, do this by medicines, but we can restrict the patient to food from which sugar cannot be readily formed. In this way, as I have already explained to you, we stay the emaciation and retard the progress of the disease; and although we exert no influence positively curative, we at least give time for the curative efforts of nature. As long, therefore, as the impairment of digestion continues, the patient should abstain from sugar, and as much as possible from all those principles, as starch and the vegetable gums and mucilages, which have nearly the same composition as sugar, and are readily converted into it. It was maintained by Dr. Rollo, who was one of the first to show the importance of diet in the treatment of diabetes, that the patient, for some time at least, should subsist entirely on animal food; and if we may judge from the cases published by him in support of his opinion, such a plan, if it could be carried out, offers a fairer chance of success than any other that has yet been tried. We might not, indeed, by this, prevent entirely the formation of sugar, because gelatine passes into sugar under

the influence of various chemical agents, though not nearly so readily as starch. But it has been found impossible by most men to restrain their diabetic patients to a diet exclusively animal. After a few days' restriction to such a diet, the craving for vegetable food of some kind becomes such, that no fears for the future will deter the patient from indulging in it.

In consequence of this, most physicians have relaxed the rigour of Rollo's treatment, and in addition to animal food, and oleaginous matters, which often agree well, have allowed the patient bread and other articles made of the flour of wheat; which is supposed by Dr. Prout to be more easily assimilated than most other farinaceous matters.

But even of the articles thus granted him, he is not allowed to take unsparingly. The craving appetite, so general in diabetes, would often lead him to overload the stomach, and increase the disorder of digestion. He is, therefore, cautioned not to take too much at a time.

He is also restricted in the quantity of liquids, which, if taken to excess, produce ill effects in various ways. They impair digestion, and they increase the quantity of urine. If the quantity of urine were increased by simple dilution, this would probably do no harm, but it is generally found that its density is increased at the same time; or if not increased in density, that there is at least an increase in the daily discharge of solid matter, which, as I have before remarked, is a measure of the exhausting power of the malady.

The fact, that drinking copiously increases the daily discharge of solids in the urine, has long been observed in diabetes; and a French physician, M. Becquerel, seems to have established by some recent observations that the same law holds in other states of the system.

The knowledge of this fact in diabetes has led men to restrict the quantity of liquids, and to recommend, instead of water, milk and animal decoctions, which, from their more cloying nature, are less likely to be taken to excess. It would seem, however, that milk is improper, from its containing a large proportion of a particular form of sugar.

Water, rendered alkaline by lime or magnesia, has also been much recommended. It often quenches thirst better than other diluents; perhaps from its neutralizing the acid, which appears to be in excess in the secretions of the mouth and stomach.

About the use of spirituous liquors opinion is much divided. In advanced stages of the disease, they are often very grateful to the patient from the temporary relief they give to the feelings of sinking and weakness

under which he labours. It is advisable that such as are taken should be perfectly dry, and contain no unfermented sugar.

Besides attention to diet, on which we must mainly rely, various other means have been found useful. The chief of these are, bleeding, opiates, and tonics.

At an early stage of diabetes, when, as often happens, the system is in a feverish state, general bleeding produces great relief, and manifestly retards the progress of the disorder. In more advanced stages, when we are deterred by the absence of fever, and by the weakness of the patient, from bleeding from the arm, cupping over the stomach, or an application of leeches, will frequently lessen the sense of heat or other uncomfortable feelings, so often referred to that part.

The effect of opiates in mitigating the symptoms of diabetes is still more striking. They are beneficial in every stage of the malady, and happily are not incompatible with any of the other means that have been found of service. They should, therefore, form part of every plan of treatment.

Tonics of various kinds—preparations of iron, quinine, carbonate of ammonia—have been much recommended, and are, no doubt, beneficial when the exhausting influence of the malady have been long continued. Their good effects are, however, far less obvious than those of opiates.

When Hawkesworth was brought into the hospital, he was placed under a plan of treatment such as I have described. He was strictly cautioned against taking sugar, or any fruits or vegetables, and was restricted to a diet of meat and bread; and for drink, milk, beef-tea, and a pint of porter a-day, was allowed him.

The absence of fever, and the weakness he complained of, deterred us from general bleeding, but soon after his admission to the hospital he was cupped over the stomach, with manifest relief to the uncomfortable feelings he experienced there.

He was ordered opium, which he has continued to take ever since; and in addition to this, the muriated tincture of iron. After some time, the muriated tincture was exchanged for the sulphate of iron, and this again for the sesquicarbonate; but neither preparation seemed to do more good than the opiate by itself. Sulphate of quinine was then tried, but produced no appreciable benefit. We next had recourse to creosote, which has been lately recommended in diabetes, and the trial of which was, I believe, first suggested by the property it has of preventing the transformation of starch into sugar under the influence of diastase. It produced no sensible benefit, and, at Hawkesworth's solicitation, was discontinued.

Under this plan of treatment, he at first improved considerably. The specific gravity

of the urine continued indeed the same (about 1040); but the quantity, which at the time of his admission averaged ten pints a-day, was reduced to four or five pints.

Towards the latter end of October the urine again increased in quantity, and during the whole of November it amounted to between seven and ten pints a day. The sp. gr. ranged from 1035 to 1045.

On the 5th of December, we discovered that he had been taking half a pound of sugar a week, which he had bought himself; and that he had availed himself of the permission we gave him to take a walk, to gratify his thirst by spruce-beer.

From this time he was confined to the hospital, and a stricter watch kept over him. The quantity of urine immediately diminished, and for the next fortnight, kept very steadily at six or seven pints a day.

On the 17th of December, acting on the opinion of M. Bouchardat, that an essential point in the treatment of diabetes is to restore the action of the skin, we put him on warm flannel dress, and gave him a hot air bath. This produced free sweating, and evidently benefited him. Since that time he has had the bath once or twice a week, and apparently with advantage. He is, at any rate, always desirous for its repetition, and tells us it invariably relieves the uneasy sensations in the stomach.

On the 27th of December, again acting on the advice of M. Bouchardat, we deprived him of ordinary bread which he had hitherto been taking, and gave him instead what M. Bouchardat calls gluten-bread—that is, bread made of flour that has been deprived of the chief part of its starch. The flour of wheat is composed of gluten and starch, in the proportion of one of the former to three or four of the latter; and the two principles may be readily separated by washing out the starch from dough.

It appears from some recent experiments of Magendie, that gluten extracted from wheat flour is of itself sufficient for the nourishment of dogs; and it seems probable, therefore, that a diet of animal food and gluten contains all that is requisite for the support of man—at least, for a considerable time. But bread made of pure gluten is so leathery—so glutinous—that it is impossible to masticate it. In order to make any thing that can be called bread, we are obliged to leave a certain proportion of starch with the gluten. The gluten-bread that we have given Hawkesworth is made by Mr. Bullock, a chemist in Conduit Street. In the first samples he sent there was one-sixth of the natural quantity of starch. In order to render it more dry and crisp the bread was made into rusks; but even in this state it was rather difficult to masticate, and Hawkesworth made great complaint of it.

Latterly, one-fifth of the natural proportion of starch, which is, I believe, the proportion recommended by Bouchardat, has been left with the gluten; and since this change was made Hawkesworth has been very contented with his bread. The bread is light, and when toasted is almost as agreeable to the taste as ordinary bread.

The substitution of the gluten-bread for ordinary bread was immediately followed by diminution in the quantity of urine, which was at once brought down to about four pints a day. The sp. gravity, however, continued as before, about 1040.

On the 4th of January we found a sudden increase in the quantity and in the density of the urine; and, after much close questioning, we discovered that he had been eating some rice-pudding, which contains sugar, and which the nurse, yielding to his entreaties, had given him.

This is the second time, since his admission to the hospital, that our endeavours to carry out this treatment have been frustrated by want of resolution on the part of the patient; and this you will find constantly happening in diabetes. In confirmed stages of the disease the patient becomes irresolute and childish, and has no strength of mind to resist the cravings of his appetite. This peculiar imbecility of mind is, probably, in some measure connected with the defective nutrition of the brain, which is so remarkable in advanced stages of diabetes. In the bodies of persons dead of this disease, the brain is always very remarkably shrunk; in consequence, no doubt, of the great wasting of all fatty matter. The void left, is, as usual, filled up with serum.

Since the 4th of January the quantity of urine has on one occasion been so little as two pints and a half in the 24 hours; but it has averaged about four pints. It has regained in some degree the natural urinous odour; but the sp. gr. has not at all diminished. It is now seldom less than 1040, and on some days 1045.

Since he commenced the gluten bread, the general symptoms of diabetes have much diminished: the appetite has become less, and the thirst is very slight, except in the morning before breakfast: his complexion is less sallow than it was, and his tongue cleaner: he says that he is much stronger, and he has certainly ceased to lose flesh.

It is evident, however, that the treatment is only palliative. The urine has still the high sp. gr. of diabetes; and the quantity he passes is as much charged with sugar as ever. All that we effect by the gluten-bread is to carry out more fully, and for a longer time than we have yet been able to do, the principle of depriving the patient of articles of food readily convertible into sugar; but we do not restore to the stomach the power

of healthy digestion. We relieve the thirst, retard the emaciation, and prevent, perhaps, for a time the occurrence of tuberculous disease of the lungs: we give longer time for the action of medicines, or for the *vis medicatrix naturæ*. This is certainly no slight advantage: it is, in fact, as much as we ever accomplish in strictly organic disease.

It seems probable, therefore, that bread made of flour deprived of a certain portion of its starch will in future form an essential part of the dietetic treatment of diabetes.

During the last week the case of Hawkesworth has presented a feature of great interest, which may perhaps render us less sanguine as to the good effects to be derived from gluten bread. I mean the occurrence of dropsy. About a week ago we noticed a slightly oedematous condition of the under eyelids, and found that he had some oedema of the feet and hands. This has increased, and at present the legs are swelled to twice their natural size. The dropsy has come on without any feverish symptoms, and at present he says that his health is as good as it has been at any time since his admission. The legs are free from pain or tenderness, and pit very readily on pressure.

The occasional occurrence of anasarca in the course of diabetes, and especially in its advanced stages, has been noticed by many writers, and has been supposed by Dr. Christison to depend on granular degeneration of the kidneys, which is met with not unfrequently in diabetic subjects. But in Hawkesworth we can detect no trace of albumen in the urine, in evidence that such a condition of the kidney exists.

Failing to discover the cause of the dropsy in granular degeneration of the kidney, we turned our attention to the heart, but have been equally unsuccessful there. The impulse of the heart is moderate, and the sounds are natural. The pulse is of moderate volume and regular; and he has at present no catarrh or distress of breathing, and there is no distension of the jugulars, to show that obstacle to the circulation through the heart exists.

We are driven then to the inference, that the dropsy depends on the condition of the blood; as it no doubt does when it occurs as a consequence of granular kidney.

It is rather singular that the last patient I had in the hospital affected with diabetes, had dropsy of the lower extremities and ascites; but this was accounted for by disease of the liver.

Of the causes of this singular malady, very little is known with certainty.

A few remarkable instances have been recorded of diabetes affecting several members of a family, and even for successive generations, which leave no doubt that a tendency to it is sometimes transmitted from

parent to child. But Hawkesworth seems to have inherited no disposition of this kind. His father was a sailor, who lived rather intemperately, but, when not suffering from the immediate effects of drink, was a healthy man. His mother is still living and hearty. He has three brothers, all living, free from eruptions, and, as far as he can judge, from any constitutional complaint. Hawkesworth himself, up to the age of 35, had uniform good health, with the exception of one attack of rheumatic fever, and was capable of great bodily exertion. There is no reason to suppose, therefore, as diabetes is not peculiar to advanced life, that he inherited any especial tendency to it. We must look for the cause of his malady in his mode of life, and in the circumstances in which he has been placed.

Dr. Prout reckons mental anxiety, venereal excesses, and the abuse of mercury, among the exciting causes of diabetes; but we have not been able to trace the operation of either of these causes in Hawkesworth. He never had syphilis or took mercury.

Residence in a damp malarious situation has also been ranked among the causes capable of exciting diabetes. Hawkesworth has spent all his life at Greenwich, which certainly is not quite free from the charge of being damp and malarious; but he never had ague, nor enlarged spleen, nor, before the accession of this complaint, the peculiar pallid and sallow complexion, and the muscular debility, which the prolonged influence of malaria produces.

Frequent attacks of rheumatism and gout have seemed in many cases the exciting cause of diabetes; but, in Hawkesworth, the diabetes can hardly be charged to the influence of either of those maladies. He never, in fact, had any gouty affection; and the only attack of rheumatism he ever suffered appears to have done him no permanent injury. He has never had the slightest recurrence of it; and he assures us, that, for ten years after this attack, he was as strong, and his health every way as good, as before it.

A prominent place among the exciting causes of diabetes has also been assigned to prolonged errors of diet, and especially to the prolonged use of diet too exclusively vegetable. To the influence of this cause Hawkesworth has been exposed. He tells us that during a great portion of his life he has been in the habit of eating large quantities of vegetables, and but little animal food. A patient that we had last year in the hospital affected with diabetes, had also been in the habit of living almost exclusively on vegetables.

The manifest effect of a vegetable diet in aggravating the disorder, when once formed, probably led to its being considered a cause

of it. The inference is not strictly logical, but I am inclined to believe that the prolonged use of a diet too exclusively vegetable may have a real influence in bringing on diabetes; not from the experience of those two cases only, but also from the exemption from diabetes that seems to be enjoyed by sailors. During the time I was physician to the Dreadnought (between three and four years) not a single case of diabetes was brought to the hospital; and it appears from the registers, which are kept with the most praiseworthy care, that, from the first establishment of the hospital, among 41,000 patients who have been treated there, there has been only one affected with diabetes.

The diet of sailors is, as you are aware, composed almost entirely of salt meat and biscuit; but it is difficult to estimate the separate influence of this, with reference to the disease in question, from there being so many other circumstances in which the life of a sailor differs from that of a landsman. Among the advantages enjoyed by the sailor, and which may have some share in procuring his exemption from diabetes, are, the pure air he breathes at sea, and the freedom from care so characteristic of the English seaman.

The concurrent operation of these powerful influences renders it impossible to separate and estimate at its just value the influence that their peculiar diet may have in exempting sailors from diabetes; but the fact of their exemption adds strength to the opinion formed on other grounds, that a diet too exclusively vegetable has a tendency to bring on diabetes.

Another possible cause occurs to us in considering the case of Hawkesworth, namely, the influence of lead. He is a painter and glazier, and two years ago he suffered severely from colic, cramps in the legs, and other effects of lead. I have often had occasion to call your attention to the great length of time lead may remain in the system, and to its powerful effect in impairing nutrition. It seems possible, therefore, that it may have some tendency to cause that weakness or paralysis of the assimilating function, in which, according to Dr. Prout, diabetes consists.

#### ILLUSTRATIONS OF THE PATHOLOGY, DIAGNOSIS, & TREAT- MENT OF OPHTHALMIC AF- FECTIONS.

By EDW. HOCKEN, M.D. M.R.C.S.L. &c.  
[Continued from p. 33].

---

WISHING to illustrate completely the subject of the varieties, causes, inci-

patient and confirmed symptoms, and the effects of treatment, in the amauroses depending on hyperæmia of the general visual nervous system, I will narrate the few remaining but condensed cases which I possess. At that period of life when the catamenia ought to occur, or at a time shortly afterwards, if they fail to be secreted, or having appeared are again suppressed by causes which derange the general health, different constitutional diseases may be established, leading to different results; either the general powers may sink, the vascular system become comparatively empty, and impoverished in its contents, with those other derangements in the economy constituting chlorosis; or, on the contrary, the vascular system may become absolutely or relatively full\*—the one with an exuberance of power, the other with a comparative deficiency in this particular. Amaurosis may occur, and does occur comparatively often, in either of these two last constitutional conditions. The relative plethora is, however, by far the more common. The following case appears to me well to illustrate the last form.

*Complete amaurosis of the right eye; imperfection of vision in the left; dull, oppressive headache; non-appearance of the menses.*

Mary Hallett, 16 years of age, was admitted into the West of England Eye Infirmary on the 21st of May, 1841. She states that for a series of years she always enjoyed uninterrupted good health, and that her habitual employments were simply confined to domestic affairs. Her sight had been failing for the last six months, especially in the right eye; in which organ she had been completely blind for the three preceding months before her admission, whilst the left has been gradually getting worse since that period. During the whole time of the existence of these symptoms, she has been subject to very severe, deep-seated, but dull and oppressive headache, especially affecting the right side. She states, moreover, that when about six years old she became blind in both eyes, and continued in this condition for about twelve months, at the expiration of which period she was perfectly cured by blood-

letting, which was employed locally, and that she has remained perfectly well ever since, until the commencement of her present attack.

*Symptoms.*—As regards her present symptoms, her countenance appears flushed, bloated, and full-looking; conjunctivæ rather more vascular than natural; both pupils widely dilated, and very sluggish in their movements, being but little sensible of the influence of light: the globes generally, and their component textures, appear healthy.

She complains of complete loss of vision in the right eye, being quite unable to distinguish light from darkness, or day from night, with that organ, and of great imperfection of sight, with cloudy, misty, and deranged appearance of objects viewed with the left eye. At present her headache is very severe; she describes it as deep-seated, oppressive, but very severe, and as affecting the right side especially. She never has been affected with intolerance of light.

Her tongue appears natural; her pulse is quick and weak, but full; her bowels regular: but she had never menstruated.

*Treatment.*—Her hair was ordered to be cut, and kept cut close, and her head to be bathed with cold water; to take the compound aloetic pill night and morning (Aloes c. Myrrhâ). She continued this treatment carefully for three weeks without any benefit.

May 11th.—Was ordered to continue the pills and bathings, with the addition of five grains of the Pil. Hydrarg. Chlorid. Comp. every night.

July 2d.—Had continued the Plummer's pill for a long time (since last date) without any beneficial result, and is now directed to take the aloetic pill alone.

5th.—Her vision remains without improvement; general powers declining. Taking these facts into consideration, with her own desire to depart, it was thought the best plan to allow her to return to the country.

*REMARKS.*—But few remarks need to be appended to the present case. It illustrates well the observations with which I commenced this paper, both as regards constitutional and local symptoms. A condition of cerebral circulation producing amaurosis had once before existed, and received its cure in the abstraction of blood; but it would

\* The remarks on the concluding case in this paper more fully explain these propositions.

appear to have been more active in its characters than the present attack. Can such local hyperæmias as the present merge insensibly into inflammation producing organic changes? and did the severe localization of the pain on the right side indicate that such had already commenced and progressed in the instance before us? That such may be the result occasionally I have not the slightest doubt, although it does not often follow on simple hyperæmias; and as regards the present case, the fixed and continued character of the pain affecting the right side, the insufficiency of treatment, and the complete loss of vision in the right eye, would lead me, at all events, to expect something of this kind. Again, however, I would refer to treatment, and again assert the great powers of counter-irritation perseveringly and judiciously employed, and which I consider a great omission in the foregoing case. I prefer blisters behind the ears, applied and then allowed to heal, and then reapplied, timely general or local blood-letting, according to circumstances, and a more full and continued action of mercury than was practised in the present instance; although it does not require a full, sudden, and powerful salivation, but a mild, persevering, constitutional use of the remedy.

*Imperfection of vision in both eyes; pain over the brows, with some intolerance of light.*

Christopher Lake was admitted as a patient of the West of England Eye Infirmary, June 22d, 1841, complaining of great imperfection of vision in both eyes. He stated himself to be 24 years of age, and to be residing at Dawlish. He has always been a stout healthy man, and stated his usual employments to be connected with shoe-making.

The account he gave of the affection is the following:—That early in the morning he can see very well, but becomes unable to keep his eyes open towards the middle of the day; that he is compelled, as he terms it, “to sleep away at his work.” At all periods he is quite unable to work by a strong light, the effects of which occasion him considerable pain in the organ; but he can work best by a dim candle-light. He complains of dull heavy pain over the brows, much increased

by exertion or straining of his sight at work, and increased in connection with pain in the eyeballs themselves by exposure to a strong light. His appearance was dull, congested, and inexpressive, with a peculiar heavy sleepy look about his eyes. Both pupils are much dilated and quite motionless; tongue clean; bowels usually regular, and digestion undisturbed; pulse full and compressible. His vision was found to be very indistinct.

*Treatment.*—June 22d. He was directed to apply the Ung. Antim. Potass. Tart. to the back of the neck with regularity, until it produced a pretty abundant eruption, and then to use it occasionally, so as to keep this up; to take five grains of the Pil. Hyd. every other night, and five grains of the Comp. Colocynth pill, with one-twelfth of a grain of the Ant. Potass. Tart. every night.

July 2d. — Rather improved in vision, &c. To continue as before.

He continued to improve on the 9th, having lost the dull pain over the brows. To go on with the same treatment.

Sept. 3d.—Vision still less defective than at previous date; but he now complains of severe pain in the head, especially over the brows: his appearance was dull, and his countenance flushed. To lose blood from the arm ad  $\text{xxij}$ .; to continue other remedies with regularity.

He had not reapplied in Oct. 1841.

REMARKS.—We may, I think, fairly presume that this was an example of amaurosis dependent on passive hyperæmia of the visual nervous apparatus generally—the cause of its production not being apparent. I come to this conclusion from the dull congested aspect of the countenance; the heavy, sleepy appearance of the eyes, and the sense of weight and oppression over the brows, as well as the indolent condition of the mental faculties, and tendency to sleep. Intolerance of light formed a prominent symptom in this case, and such I have found to be occasionally present in other forms; whilst the retina retained some powers of sensation, passing off with the increase of the amaurosis; but I am unable to account exactly for the circumstances which determine either its presence or absence. As regards the cause (exciting) which occasioned the hyperæmia, the position and occupa-

tions of the patient during his waking hours may have greatly assisted, if it did not produce, the proximate cause of the complaint, aided by a tolerably free use of exciting drinks and irregular habits, which such individuals rarely consider unusual or faulty. By the operation of remedial measures his vision was much improved, and his headache cured; but we found that on the 3d of September he presented himself with the general and local symptoms of pretty active determination of blood to the head, for which general blood-letting was employed. I presume that he was cured by these measures, or so much bettered as to think it not worth his while to present himself again.

*CASE.—Gradually increasing amaurosis of both eyes, following a sudden and severe attack of headache; slight ulcer of cornea on one eye; non-appearance of the menses.*

Elizabeth Belson, 15 years of age, was admitted as a patient of the West of England Eye Infirmary on the 26th of August, 1841. She is a tall and very stout girl of her age, of a full and florid appearance.

She states that about two years since she was seized with a sudden and very severe attack of headache, which lasted six weeks, and continued, during the greater part of that period, so severe, that her mother expressively describes her condition "as being unable to lift her head from the pillow." During this illness she was attended by a surgeon, who bled her locally, under which treatment the severity of the pain passed off; but her sight failed gradually from that date, and has continued to get worse and worse, so that at present she possesses scarcely any useful vision.

At present she complains of great defect in her visual powers, so that she is unable to walk about alone; her sight being misty and obstructed. There is present a slight ulcer on one cornea; her head appears of an unusually large size, and she is of a full plethoric habit. Her appearance is dull and heavy, especially about the eyes; her countenance bloated, and at the time of taking these notes somewhat pallid. Both pupils are dilated, and both irides act very imperfectly and sluggishly by the alternation of light and shade. She has a full pulse;

her bowels regular. She has never menstruated. She complains also of occasional pain, which affects the whole head.

Since the commencement of the existing symptoms she had been treated antiphlogistically without benefit.

She was now (August 25th, 1841) placed under the following treatment:—A weak solution of the nitrate of silver was directed to be employed as an application for the ulcer of the cornea, five grains of the Pil. Hydrarg. Chlorid. Comp. to be taken every night, and to apply the Unguent. Antim. Potass. Tart. to the back of the neck.

Sept. 3d.—Vision has decidedly improved since the last date. To continue the same treatment, with the addition of ten grains of the Pil. Aloes c. Myrrhâ every night. Had not re-applied in the middle of October.

REMARKS.—I have already made some general observations on these cases, dividing them into active and passive, and briefly illustrated my propositions by describing and commenting on a case of the passive variety. The present is obviously an illustration of the kind, and might have been narrated, after the first case in this paper, as such. I am, however, not perfectly satisfied that this condition was not preceded and primarily occasioned by actual inflammation of the membranes or brain; such a condition remaining in a subdued form, complicated with the general hyperæmia of the head, and concerned in the causation of the loss of vision, although there is no clear evidence of the fact, and mild antiphlogistic measures speedily relieved its severity. The general symptoms clearly indicated a condition of active plethora; and although "a tall and stout girl of her age," she had never menstruated; in fact, she had arrived at that period of life, in the female constitution, when it is necessary for the individual's health that this flux should exist. In the present instance, the quantity and quality of the circulating blood became excessive; a natural tendency to this condition probably existing, and in the advanced stage of this constitutional condition the local became developed. The progress I have narrated, and the effects of gentle treatment, continued for a short time, were encouraging. I have no doubt that the induction of the normal

flow of the catamenia would have been of great service.

Supposing a secretion of pus from extensive ulcers, or a loss of blood from hæmorrhoids, which, from continuance, have become habitual, to exist in any individual, it will be obvious that, unless a supply of blood were constantly furnished, not only sufficient for the ordinary demands of the animal economy in its normal condition, but beyond this, sufficient both for the wants of the system and the unnatural tax on its powers (existing in the flux), the vital powers must diminish in proportion to the excess of waste over the constitutional powers to meet the demand: so also will it be obvious that if such discharge were stopped at a time when the system had become habituated to its presence, without diminution of power by their continuance, the quantity of blood formed would still be above the normal average, and consequently accumulate in the vessels, and stimulate the inherent powers of protection to originate some actions and processes designed for its relief, whether they do, or do not, prove desirable to the health and integrity of the individual whose system is the theatre of its operations. Taking these obvious examples as illustrations, we may the more readily understand how either the suppression or non-appearance of the menses occasions a derangement in the general vascular system, since the normal constitutional powers prepare sufficient material both for the processes of life, and the habitual occurrence of the periodical discharge, so far from occasioning by the process any depression of the general tone, that it appears conducive to health; and hence, if the constitutional effort be made at puberty, but this is overcome by general or local causes, disease is sure to follow, be it general plethora of an active type, leading to its own terminations, or plethora of a passive form, with such other lesions of the nervous and circulating systems as speedily interfere with the functions of important organs, derange the secretions and excretions, and hence finally impoverish as well as poison the general mass of blood, weaken the nervous system, and disorder the whole economy: the effects being the same in nature even when the catamenia are once fully established, and then suppressed, either the results follow I have mentioned, or

a vicarious discharge is established with the object of counteracting the injurious consequences on the system of menstrual suppression.

Taking these facts into consideration we can the more readily comprehend the constitutional origin, appreciate the varieties, and the apparent uncertainty, of the derangements of vision which may occur in retention or suppression of the catamenia, as well as allow the proximity and relation which chlorosis bears to passive plethora, and "excrementitious redundancy" produced by the same predisposing and exciting causes.

[To be continued.]

### OBSERVATIONS ON THE STATISTICS OF PHTHISIS,

AND ON THE INFLUENCE OF CLIMATE AND  
OCCUPATION IN THE PRODUCTION AND  
DEVELOPMENT OF THAT DISEASE.\*

(For the *London Medical Gazette*.)

THERE is perhaps no disease which at the present time so much attracts the attention of the medical philosopher, or is so worthy the investigation it has hitherto received, and which it is yet undergoing, as phthisis. Independently of the interest created by the age and sex of those who are most commonly its victims, this disease claims especial notice from the vast extent of its ravages, not only in Great Britain, but throughout the greater part of Europe; and also from the probability there is, that, at least in this country, the mortality from phthisis is now, and has been for some years past, annually increasing.

In the present series of papers we do not intend to discuss the diagnosis or treatment of phthisis, but simply to analyse, so far, and as briefly as we can, the principal authentic statistical facts which we have at our command relating to the prevalence and fatality of phthisis in various parts of the world, and more especially in Great Britain; and thence endeavour to deduce some general conclusions with respect to the influence exerted by climate in checking or favouring the development of this disease.

\* Communicated by the author.

Notwithstanding the vast labour which has been expended on the investigation of phthisis, and the great talent which has been devoted to the task, it must be confessed that, although the diagnosis is greatly improved, and, indeed, may be said to be almost perfect, and thus the first step to a more accurate knowledge of the pathological nature of the disease made, yet no method of cure, nor even any means of prevention, have been discovered; and although nature has undoubtedly, in some few cases, of itself effected a cure, this disease has never hitherto yielded to human remedies, and still remains the true, "opprobrium medicorum."

In this state of the question it may certainly be worth while to examine those circumstances by which it would seem the frequency of phthisis is affected; and though I do not venture to hope that in the present series of papers I can contribute much towards the settlement of this confessedly difficult subject, I hope this essay may be the means of directing to this subject the attention of some members of the medical profession more competent to the task than myself; certain as I am that this method of investigating disease, and more especially phthisis, may lead to results of no inconsiderable value and importance.

The principal and most accurate source of information, as to the statistics of disease in this country, is of course to be found in the reports of the

Registrar-General, and in the important and interesting investigations of Mr. Farr, the results of which are contained in the appendices to the reports. But valuable as are these reports, they do not furnish so much information, as to the effect of climate on phthisis, as could be wished; and this is owing partly to the large area of each of the divisions or districts into which the country is divided, and in each of which almost every variety of climate experienced in England is thus to be found, and partly from the short period during which the system of registration has been in operation, and which is far too short to render it safe to rely confidently on conclusions drawn from the facts exhibited in the reports. Many years must elapse, and our knowledge of the influence of occupation on phthisis must be greatly extended, before deductions from these reports can be said to have any degree of certainty.

In the annexed table are given the total number of deaths registered in different years, exclusive of violent deaths, and those the causes of which were not specified, and the number of deaths caused by phthisis in the same years, distinguishing the sexes. The year 1837 includes only the last six months of that year; and in the Registrar-General's report for that year, the deaths are recorded under the two separate heads of consumption and decline—a distinction which is not made in the subsequent reports, and which, therefore, I have not retained.

Year.	Total number of deaths.			Deaths by phthisis.		
	Males.	Females.	Total.	Males.	Females	Total.
1837	67,949	68,726	136,675	12,968	14,786	27,754
1838	159,969	158,535	318,504	27,935	31,090	59,025
1839	159,733	158,784	318,517	28,106	31,453	59,559

From the above table I have calculated the proportion which the number of deaths caused by phthisis bears to the total number of deaths of males and females, and below are given the results, or the number of deaths caused by phthisis in each 100 deaths happening in England and Wales in both sexes, and also the proportion the aggregate number of deaths by this disease bears to the total number of deaths including both sexes.

Year.	Males.	Females	Both Sexes.
1837	19·08	21·5	20·22
1838	17·4	20·9	19·15
1839	17·5	19·2	18·65
Mean	17·99	20·73	19·36

Great as the mortality from this disease thus appears to be, it is to be feared that the above estimate is below

the truth. There can be little doubt that many deaths recorded under other heads ought to be registered under that of phthisis, in particular many of the deaths from dropsy; and Mr. Farr, in the appendix to the second report (p. 1838), remarks that "a great number of the deaths referred (1218) to hæmorrhage, and registered *rupture of a blood-vessel*, belong to consumption."

Taking the mean of the years, the number of deaths in which are given above, it appears that 19·36 per cent. of the total number of deaths, or nearly one in five, is caused by phthisis. If to this we add the number of persons whose lungs are found on examination after death to be tuberculous, and which is stated by some authorities, and, if I remember right, by Louis, to be in the proportion of one-sixth\* of all those who die of other diseases, we find that nearly one-third of the total number of deaths (subject to the exception with which I set out) are those of persons who either die of, or are labouring under, phthisis at the time of their death.

The comparative tendency to phthisis in the two sexes has been calculated by Mr. Farr by taking the ratio which the number of deaths from phthisis in 100 deaths of males, and in the same number of deaths of females, bear to each other. Estimated in this manner, the mean per centage of deaths by phthisis of males and females being 17·99 and 20·7 in the two years and a half, would give the number 1·14, as expressing the tendency to consumption in the female: the tendency in the male being taken as unity. The above, however, is not a very exact method of exhibiting the comparative tendency to phthisis in the two sexes. A more accurate estimate is, in my opinion, obtained by comparing the actual mortality from phthisis in the two sexes,

\* According to Dr. C. J. B. Williams, in a recent number of the *MED. GAZETTE*, the proportion is much larger. He observes: "I am convinced, from extensive observation and much reflection on this subject, that tuberculous disease of the lungs, in some degree or another, in one form or another, prevails among the more seriously sick in London, and in other large towns, in as great a proportion as among our own patients (1 in 3·5). So far as our own post-mortem examinations have given the opportunity, you have seen verified the statement which I have made, that of those in large towns who die of various diseases or accidents, above the age of thirty, more than half exhibit in the lungs more or less of tubercular disease, or of the traces which it leaves behind."

with the number of persons of each sex living at the time. Estimated in this manner, the results are rather different from those of Mr. Farr, and lead to the conclusion that the difference in the mortality from phthisis in the two sexes is not so great as stated by him, and as is generally supposed.

The population of England and Wales in 1831 and 1841 respectively is given below, and indicates an annual rate of increase in the whole population of 14·525 per cent. in the ten years, or, assuming the population in 1831 as unity, an annual rate of increase of ·014525: taking, in the same manner, the male population in 1831 as the unit, the table shows a rate of increase = ·01483 of the males; while, in the same way, the annual rate of increase of the female population, in the ten years ending 1841, was ·01422. These rates of increase are much below those which took place in the ten years ending 1841. We have supposed the rate of increase uniform, or an equal number added to the population in each year. There can be no doubt that this supposition is incorrect, and that the rate of increase has been gradually diminishing; yet, nevertheless, a tolerably exact estimate of the population is thus obtained, and a result sufficiently near the truth is, for our purpose, perhaps, obtained.

The population returns in 1831 and 1841 give the entire population as follows:—

	Males.	Females.	Total.
1831	6,769,469	7,125,105	13,894,574
1841	7,773,411	8,138,314	15,911,725

Calculating the population in the intermediate years in the manner just explained, we shall find the population, at the periods to which the Registrar-General's reports extend, to be as under:—

	Total.	Males.	Females.
1837	15,105,482	7,372,470	7,720,105
1839	15,307,300	7,472,970	7,821,423
1838	15,509,118	7,573,470	7,922,741

Taking the above numbers to represent the actual population at the respective periods, the annual mortality

from phthisis in each 100 males living in England and Wales,

was in 1837 .....	351796
1838 .....	373814
1839 .....	377440
<hr/>	
Mean =	367683

The mortality from phthisis in the female sex is higher, and in the same years this disease caused a mortality in each 100 females living,

of .....	383052	in 1837
.....	397498	1838
.....	396996	1839
<hr/>		
Mean =	392515	

The comparative mortality from phthisis in the two sexes thus appears to be, taking the mortality in the male sex as unity, in the ratio 1·0675 to 1; or, in other words, consumption is in this country rather under seven per cent. more fatal to females than to males.

Viewed in this manner, the difference in the fatality of phthisis to the two sexes is, as we have before remarked, much below what has been generally supposed. Either of the above methods of estimating the comparative fatality of any disease in the two sexes may, of course, find advocates for their correctness; but I am disposed to believe that the last mode of calculating the amount is the one which gives the result nearest the truth. If we calculate the comparative tendency to phthisis by taking the proportion the deaths by phthisis form of the total number of deaths in each sex, which is the mode adopted by Mr. Farr, a result is obtained differing very considerably above, the tendency in the female being thus 14 per cent. greater than the male.

We have before remarked that from the great extent of each of the districts referred to in the Registrar-General's reports, so much information as to the effect of climate on phthisis cannot be gathered as would be obtained were the districts of a smaller size. In different parts of the same county in England we may generally meet with almost as great a difference in climate, both with respect to temperature and dryness, as is to be found in wholly different and distant parts of England, and thus the effect of climate is not so distinctly shown in the reports as it would be, were it possible to compare

the mortality in numerous small tracts of country enjoying the same or a different climate.

That certain small spots or districts of country are remarkable either for the frequency of phthisis among the inhabitants, or their freedom from that disease, is a fact which we ourselves have noted. Mr. Thackrah, in his very interesting work\*, has thus remarked the great frequency of this disease in the neighbourhood of Bradford. But, with respect to this particular locality, Mr. Thackrah makes an additional and very curious observation, which I think it is worth while to stop to notice. In speaking of the well-known forges in the neighbourhood of that town, and the health of the workmen employed at them, he remarks that, "Notwithstanding the great transition to which founders are exposed, we did not find that they are particularly subject to acute diseases. We were informed that they are rarely off work, except from intemperance. Consumption is said to be exceedingly rare in the neighbourhood of the iron-works." The statement made in the last part of this extract appears to be confirmed by another observer; for the writer, in a note, adds, "Dr. Macturck, of Bradford, who, from his vicinity to the iron works, is well acquainted with the subject, has been kind enough to review these observations. He states them to be correct. He thinks that consumption, though the peculiar scourge of Bradford and its neighbourhood, is comparatively rare among iron-founders."

This circumstance, if a fact, which it thus appears to be, is certainly worthy of notice, and is the more curious if, as we believe, iron-founders are not, in general, more free from pulmonary complaints than other classes of operatives. Ramazzini has discussed the subject of the health of smiths, but as the persons to whom his observations apply were merely common smiths, and not persons employed in bloomeries, his remarks do not bear very immediately on the subject. "Innerliche krankheiten der Brust," says Ramazzini†, werden bei Eisen-schmidten nicht allzu häufig angehoffen."

\* The Effects of the principal Arts, Trades, and Professions, on Health and Longevity, &c., p. 77.

† Abhandlung von der Krankheiten der Kunst-

The mean duration of life among smiths would, however, appear to be shorter than the average of other classes of persons. The researches of M. Lombard\*, who has discussed with remarkable sagacity the deaths happening at Geneva, assign a period of 56·3 years as the mean duration of life at that place, whilst he gives 54·5 years as the mean duration of the life of smiths.

The iron forged at the works near Bradford is the celebrated Bowling or Low Moor Iron, so well known to, and highly prized by, every engineer for its tenacity and toughness; and it should be remarked that these qualities, on account of which it excels every other kind of British iron, are owing to the considerable proportion of arsenic which it contains; a metal absent in most sorts of iron. On the chemical constitutions of this iron Dr. Schafhaeutl remarks†, "that the best irons of Sweden contain a considerable quantity of arsenic, and the celebrated English *Low Moor* iron contains still more. By forging the best English cast steel, arsenic is volatilized, and may be easily detected by the smell; and the blacksmiths who forge *Low Moor* iron frequently complain of the unpleasant smell which escapes, by them termed a sulphureous smell, causing them often swelled lips."

We must not, however, (more particularly as Mr. Thackrah has furnished no numerical data) from this single fact, conclude that this metal exerts a protective power against phthisis, and the above observations must not, therefore, be understood to be urged as any proof that this metal has power, when absorbed into the human system, of warding off the incursions of this perhaps the most formidable and fatal disease to which the human species is exposed. I consider the peculiar freedom of the workmen at the Low Moor works from phthisis, while they are exposed in a remarkable degree to the influence of arsenic, only as a fact singular in itself, and which deserves to be contrasted with the supposed effects of arsenic in other places and under different circumstances; and I hope that the present notice of this fact may lead some of the readers of this jour-

nal who, by residing in the neighbourhood of copper smelting works in Wales, or near iron bloomeries, have the opportunity of investigating this subject, to turn their attention to the point.

The miners in some parts of Germany, particularly those employed in the preparation of smalt, and the copper smelters in Wales, are much more exposed to the fumes of arsenic; but I have not been able to learn, as far as concerns the latter class, whether, as amongst the iron-founders at Bradford, any peculiar exemption from phthisis obtains. Ramazzini, however, distinctly asserts, that the fumes of arsenic are not only highly injurious to the workmen employed in the cobalt mines of Germany, but also that the absorption of this metal frequently induces consumption. He observes that care is taken to prevent the fumes escaping, the arsenic being condensed or sublimed in the process of roasting in long wooden pipes\*: "wobei aber niemals verhindert kann, dass nicht ein Theil der Rattenpulverdämpfe in die Lungen der Arbeiter, besonders derer, die das Feuer behandeln, gelangen sollte, welche auch nach Henkel's Zeugniß fast insgesamt von Engbrüstigkeit, Keichen und Husten befallen werden, welche Zufälle oft zehn bis zwanzig Jahr lang, bis an ihrem Tod dauern, das Leben allemahl, aber unstreitig, wegen der Arbeit im Freyen, nicht so mächtig als die Grubensarbeit verkürzen, und endlich insgemein, nach einem mühseligem Lebee, die Lungen sucht, ein auszehrender Fieber und der Tod verursachen." At the time when the preceding extract was written the diagnosis of phthisis was very imperfect; and we surely think, from the above account, that the characters of the disease are those of true tubercular phthisis.

In conclusion, I fully coincide in, and feel the force of, the observation on the discovery and selection of remedies for this disease, inserted in the English translation of Louis on Phthisis. "The difficulty of the inquiry is immense, and much caution must be shown in arriving at general conclusions: on the other hand, the hopelessness of the disease, and the insufficiency of every known treatment,

fully justify experiments in search of a new remedy." Undoubtedly, when we consider the fearful mortality from phthisis, and the age at which it most commonly attacks its victims, experiments appear to be justifiable; and a successful mode of treating this disease to be the great and most important advance yet remaining to be made in the art of medicine. "*Et profecto, si hominibus unquam liceret gloriari, certe de hoc maxime gloriandum esset, tantum scilicet profecisse genus suum, et tam præclarum tamque perenne existere ingenii humani monumentum.*"

---

ON THE  
VITAL PROCESSES AND THE IN-  
FLUENCE OF THE ATMOSPHERE  
UPON ANIMALS.

BY PROFESSOR LIEBIG.

Translated from the "*Annalen der Chimie und Pharmacie.*"

---

THERE is in animals and plants a power which may be supposed at rest, but which, when active, is the cause of the increase in mass and of the repair of the substance which is used. By means of external circumstances the static power of this activity is increased. This power when in action is evidenced in the formation of a series of products which, though they are sometimes inclosed in straight lines, yet are they far removed from those geometric forms which we see in crystallised minerals. This power is called vital power. The increase in mass of plants depends on a decomposition which proceeds in certain parts of them under the influences of light and heat. In the vital processes in plants, inorganic substances without exception are submitted to this decomposition; and if we may reckon, as the most distinguished mineralogists do, the air and certain other gases as minerals, we may say that the vital activity in plants effects the transformation of the mineral into a body endowed with life. The mineral takes part in the support of the vital power. The increase in mass in a living plant presupposes that certain components of the food become components of the substance of the plant; and a comparison of the chemical com-

position of both shews with certainty which of the components of the food pass away, and which are assimilated. The observations of vegetable physiologists and the investigations of chemists have mutually proved that the increase and development of plants depends on a separation of oxygen from the constituents of their food. In exact opposition to vegetable life, animal life shews itself in a never-ceasing absorption and combination of the oxygen of the air with certain components of the animal body. While no part of an organic body, unless it first take an inorganic form in consequence of putrefaction or decay, can serve for the nourishment of a plant; an animal requires for its support and growth more highly organised atoms. The food of all animals is, under all circumstances, organised.

An animal is distinguished from a vegetable by its power of motion, and generally by sensation. These modes of action proceed from certain organs which are wanting in plants. Comparative anatomy shows that motion and sensation depend on certain apparatuses, which are only related by being united in a common centre; and the substance of the spinal cord, the nerves, and brain, are, in their composition and chemical relations, remarkably different from the substance of the cellular membranes, tendons, muscles, and skin. All that can be called motion in the animal body proceeds from the nervous system. The motions in plants, as the circulation of the sap in some *Charæ*, the closing of flowers and leaves, depends on physical and mechanical causes. A plant contains no nerves; in it warmth and light are the remote causes of motion; while in animals we see in the nervous system a source of power which is able during life at each moment to renew itself. Both in the assimilation of food by plants, and in their whole process of formation, there is a dependence on certain external influences which produce motion; whilst the growth of the animal body is, up to a certain point, independent of these external causes, because the body produces within itself, by a special system of apparatus, that power of motion which is indispensable for life.

The processes of formation, assimilation, and the transition of those sub-

stances which are in a state of motion into a state of rest, proceeds in the same way in plants and in animals. It is the same cause, namely the peculiar vegetative life, which acts without consciousness, that determines in both the increase in mass. The vegetative life makes itself known in plants by the help of external influences, but in animals by means of influences produced within themselves. The circulation of the blood, secretion, and digestion, are each subject to the nervous system. But it is one and the same power which gives equally wonderful properties to the germ, to the leaves, and to the fibres of the roots, as to the secreting skin and the glands, or to each organ, rendering it capable of directing its own function; only the causes which set them in motion are in the two cases different. Whilst we always find in the lowest classes of animals organs of motion, we find, in the highest, organs of feeling and sensation, of consciousness and reason. The pathologist shows us that the proper vegetative life is by no means confined to the existence of these organs; that the process of nutrition proceeds in the same way in those parts of the body where the nerves are paralysed which communicate sensation and voluntary motion, as in others in which they exist in a normal state; and, on the other hand, the strongest action of the will can exercise no influence over the contraction of the heart, the peristaltic action of the bowels, or the process of secretion.

The phenomena of the mind cannot be explained as to their proximate, still less as to their ultimate causes, by our present principles of knowledge. We know no more than that they are in existence. We ascribe them to an immaterial energy; and indeed, so far as their manifestation is united with matter, we ascribe them to a power which is quite different, having nothing in common with vital power. This peculiar power, it cannot be denied, exercises a certain influence on the activity of vegetable life, similar to that exercised by immaterial forces—as light, electricity, warmth, and magnetism; but this influence is no settled property, and only makes itself known by accelerating, disturbing, or retarding the activity of vegetable life. In

an exactly similar way the activity of vegetable life reacts on the mind.

There exist two powers which are in action dependent on each other; but consciousness and reason may be wanting in animals and plants, without our missing any thing else in them excepting the absence of a peculiar cause of increase or diminution of action. With the exception of this, the chemico-vital processes in men and animals proceeds exactly in the same way.

The often-renewed attempt to explain the connection of the mind with the animal life has always retarded the progress of physiology. It is a continual departure from the realms of natural science into the empire of imagination. Thence the inspired physiologists were very far from recognizing the laws of the purely animal life. Not one of them had a clear conception of development or nutrition, or the real causes of death. They gave explanations of the most secret physical phenomena, and were not able to say what fever was, and how bark acted. To explain the laws of motion in the animal body the knowledge of the apparatus was the only thing investigated, which only communicates the motion; but the substance of the organ, the changes which the food undergoes in the living body, its transition into the constituents of the organ and again back into inanimate combinations, and the part which the atmosphere takes in the vital processes,—all these first principles were not considered.

What has reason, consciousness, or the soul, to do with the development of the foetus or with the young chick? certainly not more than in the development of the seed of a plant. Let us endeavour to refer non-physical phenomena to their ultimate causes, and let us be cautious of drawing conclusions before we have first principles. We know well enough the mechanism of the eye; but neither anatomy nor chemistry will ever explain why a ray of light attains to consciousness. The investigation of nature has certain bounds, which must not be transgressed. It must be always remembered, that in all our discoveries it can never be known what kind of things light, electricity, and magnetism, are; for the mind of man can only conceive those things which are material. We can inquire into the

laws of their conditions of rest and motion, because they are evidenced by phenomena. So, without doubt, can the laws of life, and all that interrupts, advances, or changes them, be inquired into, without our ever knowing what life itself is. The inquiry into the laws of the fall of bodies, and of the motions of the heavenly bodies, led to a previously unconceived idea of their cause. This idea could not have arisen in clearness without a knowledge of the phenomena from which the laws are developed; by itself the force of gravity is what light is to one born blind, nothing but an empty word.

The new science of Physiology has left the Aristotelian method; it allows no more *horror vacui*, no longer a fifth essence to give to credulous listeners explanations and interpretations of phenomena whose proper connection with other phenomena, and whose ultimate causes, are not made known to us.

If we hold the belief that all the phenomena in the bodies of plants and animals must be ascribed to an entirely peculiar cause, which is quite different from all other causes which produce change of condition and motion, and if we allow that the vital power is a power existing for itself, then we shall have, in the phenomena of organic life, as in all other phenomena which can be ascribed to power, a static state, that of equipoise depending on an opposing force and a dynamic state. All parts of the animal body are formed from a peculiar fluid circulating in the body, in consequence of an inherent activity in each cell, in each organ, or part of an organ. For physiology teaches that all the components of the body were, in their origin, blood, or that they were at least supplied to the existing organs by that fluid.

The most ordinary experience further shows that, during each moment of life, there proceeds a perpetual more or less rapid change of material in the animal body: that one part of the structure resolves itself into matter without form, losing its condition of life, and this must be again renewed. Physiology has decided reasons for thinking each motion, each expression of power, is the consequence of a decomposition of structure. That each idea, each pas-

sion as a consequence, effects changes in the chemical condition of the secretions, that each thought, each feeling, is accompanied by a change in the condition of the brain. For the support of the phenomena of life in animals, there are required certain materials, portions of organized bodies, which we call nourishing substances. By means of a series of changes, these serve either for increase of mass (nourishment), or for compensation for materials used (reproduction); or they serve for the production of power.

If we call the taking of food the first condition of life, the second is a constant absorption of oxygen from the atmospheric air. According to the principles of the natural philosopher, animal life makes itself evident in a series of phenomena, the continuance and repetition of which is caused by a change which the food and inspired oxygen of the air undergo in the body by the co-operation of the vital power. All vital activity arises from the reactions of the oxygen of the air and the constituents of the food. In the processes of nutrition and reproduction we recognise the transitions of matter from the state of motion into the state of rest (the static equipoise). By means of the influence of the nervous system, this matter acquired motion. The ultimate causes of these different states of vital power are chemical powers. For the cause of the state of rest is an obstacle which depends on a power of attraction (combination), which acts between the smallest particles of matter, and becomes evident only at immeasurably small distances, or in immediate contact. This special kind of attraction can, naturally enough, have different names. The chemist calls it affinity. The cause of the state of motion lies in the series of changes which the food undergoes in the body: in consequence of a process of change which the food itself, or the structures which arise from it, or the constituents of the organs, undergo.

The principal character of the vegetative life is a continual transition of the matters which are in motion into a state of static equipoise. So long as the plant lives there is no stoppage of increase to be remarked; no part of the organs of the plant decreases in mass. If any decomposition takes place, it is

a consequence of assimilation. A plant produces in itself no power of motion. No part of its structure loses its vital state, in consequence of a cause existing in its own body, and then passes over into combinations without organic form. No consumption of substance occurs in them. The consumption in animals is from change of condition, and from the decomposition of certain constituents of the animal body. It proceeds, consequently, by means of chemical action. The power of poisons and medicines over the living body evidently shows that the processes of chemical decomposition and combination in the animal body, which are known to us as vital phenomena may be increased by chemical power acting in the same way, and retarded or abolished by that acting in an opposite way; and that we can exercise an influence on each part of the body by substances possessing a determined chemical action.

Analogous, therefore, to the closed galvanic circle, by means of certain changes which an inorganic body, as a metal, undergoes by contact with an acid, a certain something becomes perceptible to our senses, which we denote by a current of electric fluid. So, from the decomposition and change of matter which formerly was part of the body, certain appearances of motion and action take place which we term life. The electric current makes itself known by means of certain phenomena of attraction and repulsion, which other materials, in themselves motionless, receive thereby; and it is known by certain phenomena of the formation and resolution of chemical compounds which appear everywhere, if obstacles do not hinder motion. From these principles alone, and from no others, ought the chemist to study the phenomena of life. We find cause for wonder in every thing; the formation of a crystal, an octohedron, is not more incomprehensible than the origin of a leaf or muscular fibre; and the formation of cinnabar from mercury and sulphur is quite as inexplicable as the formation of an eye from the substance of the blood.

[To be continued.]

## MEDICAL GAZETTE.

### THE SPIRIT OF MEDICAL REFORM.

*Est modus in rebus; sunt certi denique Fines,  
Quos ultra citraque nequit consistere Rectam.*

IN these lines the poet has embodied a sentiment which few are disinclined to assent to in the abstract, but many are apt to disregard in practice. If, at the end of this dry precept, he could have pointed out in what the *modus* consisted, where those *certi fines* were to be discovered, he might have gained the additional honour of having saved posterity from the exhibition of no small amount of folly, and from the consequences of many extravagant opinions and actions which they have to regret. The bequest of a standard for our conduct, to which we might refer upon all occasions, and under all changes, would be too rich a legacy to expect from any one, who was not himself free from human imperfections. Let us, however, recommend the condensed and important maxim he has left us, where it seems to apply; and we think it may with advantage be adduced in opposition to the restless spirit of the time, which is so averse to any thing like a moderate and dispassionate view of a subject, and also in refutation of those hasty and extreme opinions which are incessantly brought under our notice. The cry throughout the political world has long been that of reform; and we cannot be surprised that a voice so popular should be heard within the sphere of medicine, especially as so many evils confessedly exist in our profession, which have long demanded revision and correction. What those evils are, we have already endeavoured, in several previous numbers, to

bring before our readers, with such comments as seemed most likely to excite attention to them, and with such proposals for their improvement, as in our judgment were best suited to meet the present emergencies. Of good and sound reform we have ever been, and shall continue to remain, the consistent supporters, being fully aware of its necessity, and of the advantages to be derived from it. We have long seen the evils under which the practitioners of this country labour, and should rejoice in the prospect of seeing them relieved; at the same time we by no means assent to the bold proposition, that all change is to be esteemed as reform, but feel it incumbent on us to repudiate the exorbitant demands of those, who, not content with safe and moderate measures, are ever bringing forward preposterous and dangerous schemes, and who, not satisfied at the introduction of such regulations as may establish more securely, and render more efficacious, our present systems, are anxious to demolish those systems altogether, and to build on their ruins various chimerical projects of their own invention. When once the tide of reform has fairly set in, it requires no moderate force to turn it aside: it usually works its way in spite of all opposition, till at length we have cause to fear, not that we shall have no reform at all, but that we shall have too much. Even its best and most cautious promulgators are liable to transgress the limits which prudence dictates; and much more have we cause for apprehension from the ill-judged measures of those who are satisfied with nothing short of universal changes and wholesale abolitions. When the grievances under which practitioners suffered were first brought into notice, and the inefficiency of our corporate bodies to afford them full protection was made public, a spark was kindled which has by degrees been

fanned into a flame; and the apprehension we now entertain is, that the eradication of the evil complained of, will not be effected without the destruction of much good, which might remain. Reform in medicine may be said to have fairly commenced in 1833, when the College of Physicians, aware of the necessity of the case, proposed and adopted some measures for the furtherance of the general good; but the cry had gone abroad, and could not be appeased, except by changes of greater moment. It has ever since been heard at intervals, gradually progressing, till it has surpassed the bounds of reason, and now threatens to abrogate altogether our present system of administration, and to extirpate the Colleges, which have so long directed the helm of our affairs, and maintained the respectability of the profession.

We are far from subscribing to the opinions of those who place implicit reliance in the so-called wisdom of antiquity; at the same time, we must insist that existing institutions and customs do appear entitled to respect and deference, from the very circumstance of, and in proportion to, their antiquity. The period during which they have stood the test of time, and the attacks of violent men, in periods both of revolution and of peace, is a decided testimony in their favour—nay, more, it is a powerful argument for their preservation. If they have been so long serviceable to the ages and to the men they have survived, they ought to have credit given them for the capability of being continued with advantage; and surely this is no small argument to tender in opposition to the caprice and fancy of an innovator. It is sufficient, surely, to throw upon him the *onus probandi*—the duty of proving, to the satisfaction of those who are interested in the question, not merely the insufficiency or deficiency of what exists, not merely

that what he seeks to change is trite, old-fashioned, and ill adapted to the present time, but the obligation of clearly demonstrating, that what he proposes in its place, is not simply an alteration but an improvement—that it is remedial, and that it will not only supply the place of its predecessor, but that it will answer its purpose much better. Yes, we say it lies upon him not only to show the insufficiency of the thing removed, but to bring good evidence of the sufficiency of the thing substituted. We all know how easy it is to find fault, but the discovery of defects, though calculated to give men a great idea of their own talent and quick perception, is not of itself sufficient condemnation of what has fulfilled its required purposes for any length of time. Further, as each alteration of any long practised custom, especially if suddenly made, is generally attended with inconvenience to some, and the more radical the alteration the more extensively is the inconvenience felt, it becomes necessary to show that the benefits proposed will be commensurate. Unless there be rational grounds for supposing that the good to be derived from a change, will more than counterbalance the evil occasioned, one fundamental principle of reform must be wanting. In these remarks our object is solely, to restrain the desire of seeking and producing extreme measures, as well as to oppose that “*natura novitatis avida*” which is constantly endeavouring to introduce change, without a proper regard for improvement. We would not in any degree detract from the merit of those persons whose writings in this, and other journals, evince that their authors have well weighed the subjects on which they treat, and pronounce them to be in intention, if not in reality, benefactors to the profession. Such men deserve our warmest thanks for the assistance

they have rendered in promoting the great object of rational reform.

In medicine, more particularly than in any subject, should reform be instituted cautiously. The public and the profession are so closely bound up together in the existing usages, that a new system of regulations, which has for its purport the advantage of the one, may, in many instances, tend directly to the injury of the other. The existing divisions of the profession, for example, appear so evidently to have originated as the means best adapted to supply the wants of the public, as well as to forward the interests of science, that an unnecessary interference with them would undoubtedly be attended with inconvenience to both. In allusion to this subject, we may refer to a series of letters on the “Division of Medical Labour,” which have recently appeared at intervals in the pages of the *Gazette*, from the pen of Dr. Hull. They contain much sound practical observation, with many good arguments in favour of the present position of things, and show forcibly the evil which would attend on the amalgamation of the different branches of the profession.

It was with these feelings that, in a former number, we ventured to give our *general* approbation to the Bill of Sir J. Graham, which appears, so far as we have been able to ascertain its nature, to have the merit of avoiding extremes, and to have for its object the giving greater force to our Colleges, by removing some of the defective points in their organization, and thus rendering them more serviceable to the profession at large. The principle of this Bill appears to be confirmative rather than destructive; and we are rejoiced at being able to discover some probability of the questions, which have long agitated the medical world being at length decided on such safe grounds

as are proposed in it. It gives us some anchorage on which to rest in the troubled sea of discontent and danger—of doubt and perplexity, in which the profession has so long been embarrassed. While our best institutions are in jeopardy, and while attempts are constantly made, by the introduction of sweeping measures, to subvert those systems to which we are attached by time, and the advantages we have practically derived from them, it is no wonder that we are glad to rest upon any proposal, which, taking a moderate course, offers to restore tranquillity, and, at the same time, to better our condition. The Bill may in many points prove defective\*; and we must expect that, to a certain extent, such will be the case with any measure. The emergencies to be met, are so numerous that we cannot with reason anticipate that every object should be attained; and while conflicting interests are so various, while propositions from all quarters have been so numerous, we must be prepared to find that many will be dissatisfied. Alterations and revisions will doubtless be required in several of its clauses, before it be allowed to pass into a permanent act; but into the consideration of these we do not propose now to enter: we merely here repeat our approbation of the *general* principles on which it proceeds, in opposition to the outcry which has on many sides been so virulently urged against it.

#### ALLEGED DEATH FROM SALIVATION.

A CASE which was the subject of much interest, and some popular excitement, has recently occurred at Durham. The wife of one of the pitmen was attacked with symptoms which ended in typhoid fever, with gangrene of the cheek, and proved fatal. She was attended, in the first instance, by Mr.

\* See the letter of "A Surgeon and Apothecary," page 187 of our present number.

Hopton, a highly respectable surgeon in Durham; afterwards by Mr. Oliver; and, lastly, by Mr. Green. It appears from the evidence, that the gentleman first mentioned prescribed calomel, and to this the subsequent symptoms and fatal result were attributed. We have looked over the statements of the various witnesses, including the medical men, and are perfectly satisfied that there was no ground whatever for the charge, or rather, perhaps, insinuation, against Mr. Hopton; and for these reasons—first, that he gave very moderate doses of the mercury; and, secondly, that the symptoms were not such as result from that agent, the swelling and sloughing being confined to the upper jaw, while the gums of the lower jaw continued throughout entirely unaffected. The evidence of Mr. Green was perfectly straightforward and satisfactory; and we are happy to add that the verdict of the jury bears the same character; namely, that "the deceased came to her death from gangrene consequent upon typhus fever." Mr. Hopton thus stands entirely exonerated from blame.

#### COLLEGE OF SURGEONS.

WE understand that the Council have decided on recognising certificates from no Metropolitan Hospital with less than a hundred and fifty beds, and of no Provincial establishment having less than one hundred.

It is said that a series of *Conversazioni* are to be given at Lincoln's Inn Fields: if so, we hope they will answer better than did those at the College of Physicians.

#### UNIVERSITY COLLEGE.

##### PROFESSORSHIP OF MIDWIFERY.

WE learn that Dr. Murphy, of the Lying-in Hospital, Dublin, has been appointed successor to Dr. Davis, as Professor of Midwifery in University College.

#### STUDY OF INSANITY.

(From a Correspondent.)

UNDERSTANDING that Dr. Conolly, resident physician at the Hanwell Lunatic Asylum, has announced his intention of giving a course of lectures on insanity to a select number of medical pupils from the different London hospitals, we must acknowledge our satisfaction at this announcement, as it forms a new and important step to promote medical education, whereby the knowledge of a very interesting

and most prevalent class of diseases may be usefully extended amongst the rising members of the medical profession; the investigation of which maladies has hitherto been too much overlooked by the general student during his preliminary education, and afterwards by the majority of medical practitioners.

Unquestionably it does appear rather singular that in this country, where, unfortunately, so much insanity prevails in all ranks of society, from the pauper to the peer, nevertheless until of late very little attention has been directed to the diffusion of information, or to the instruction of students, in mental diseases; neither has any effectual attempt been made to render the great public establishments for the reception of the insane in the metropolis available for the purpose of investigating the pathology and curative treatment of insanity; as, for instance, Bethlem Hospital with upwards of 300 patients, St. Luke's with more than 200 lunatics, and the Hanwell Asylum, where nearly 1000 insane patients are at present accommodated.

These extensive fields for knowledge, having upwards of 1,500 insane patients, and where every variety of mental diseases must be constantly met with, have hitherto been almost entirely as sealed books to the great body of the medical profession, and consequently entailing a very serious loss to the community at large, who have the greatest interest in possessing experienced practitioners in this as in other diseases. However, it is satisfactory to learn that at last a new system is about being commenced; and should the example thus set at Hanwell be also imitated at St. Luke's, or at Bethlem Hospital, the benefit conferred by such proceedings will be important, and in every way most advantageous. Indeed, it appears that at Bethlem a similar feeling already prevails, since at the Quarterly General Court of the Governors of Bridewell and Bethlem Hospitals, held in January last, according to a report of the meeting given in the Morning Herald of Friday the 28th of that month, the idea of allowing a more free admission than heretofore to medical students into the wards of that richly endowed and well-regulated institution, for the purpose of study, was incidentally the subject of discussion; and judging from the remarks made on that occasion, the proposition was rather favourably received.

The question of granting admission to students to investigate and to learn the treatment best adapted for mental diseases in the wards of the metropolitan lunatic asylums, is one of great interest, and well deserves serious consideration, and would certainly be attended by the best effects to the community, whilst it would constitute a great

boon to those about to engage in the practical duties of the medical profession. And although some governors, from dislike to new measures, or their timid disposition about changing the present system, might entertain doubts or fears on the subject, lest such an innovation might act injuriously on the afflicted inmates of a lunatic asylum; such apprehensions would prove groundless provided the plan were carried out judiciously, and under proper regulations, lest even if a few patients were excited by the presence of young men accompanying the attending physicians during their stated visits to the wards, that is only a very partial evil, not at all to be put in comparison with its many other advantages. To pursue the subject any further appears unnecessary, trusting that the question will soon be better understood; in the meantime the proposed course of lectures intended to be given at the Hanwell Asylum is highly creditable to Dr. Conolly, and must have considerable weight as an example to the medical officers of other insane establishments, which they would do well to imitate.

## LICENSED LUNATIC ASYLUMS BILL.

### STATEMENT OF OBJECTIONS TO THE PRO- VISIONS OF THE BILL.

THE following objections to the above Bill, now pending in the House of Commons, intituled, "A Bill for amending the Laws relating to Houses licensed by the Metropolitan Commissioners and Justices of the Peace for the Reception of Insane Persons," are respectfully submitted to the consideration of Members of Parliament by an Association of Members of the Medical Profession who are proprietors of Provincial Lunatic Asylums.

By the above-mentioned Bill it is proposed to provide that all private Provincial Lunatic Asylums, and every patient confined in them, shall, in addition to the visits required to be made by the magistrates under the Act of the second and third years of the reign of King William the Fourth, be visited at least three times in every year by a Commissioner, whose only qualification for the office is to be his admission to practice *as a barrister-at-law*; which Commissioner is to have power, if he think fit, to call in the assistance of any medical practitioner, of whatever grade, whether physician, surgeon, or apothecary, provided he be not appointed by the justices at quarter sessions a visitor of the Lunatic Asylum to be inspected, or interested therein, and with the concurrence of such person, after *two* visits, to order the discharge of any patient confined in such

Asylum, who shall not have been found a lunatic under any commission issuing out of the Court of Chancery, or shall not be confined under the order or authority of Her Majesty's principal Secretary of State for the Home Department.

It is submitted that such provisions are inexpedient as regards the proper care and treatment of lunatic patients, derogatory to those members of the medical profession under whose charge such members may be placed, and fraught with danger to the public.

Provincial Lunatic Asylums are now by law subject to inspection three times every year by magistrates duly appointed, and by medical men of eminence selected for the purpose by the justices assembled at the quarter sessions for the counties in which such asylums are situate, and the system of visitation thus instituted has, it is believed, when duly carried out, fully answered the purposes for which it was intended.

The powers of the magisterial visitors are to remain unrepealed by the present Bill, and the decisions of the new tribunal to be created in the person of a Barrister Commissioner, accompanied by any medical man whom he may call to his aid, may therefore be frequently at direct variance with that of the magistrates and their sworn physician.

The frequency of the visits to lunatic asylums which would be occasioned by the proposed Bill are calculated to keep up a degree of excitement in the patient, detrimental to his proper treatment, and obstructive of his recovery.

It is often difficult, with the greatest nicety of medical discrimination (especially in cases of convalescence), to detect the presence of this most insidious disease, of which fact the public Reports of the Metropolitan Commissioners in Lunacy afford sufficient evidence, inasmuch as it thereby appears that, notwithstanding great care and precaution on the part of such Commissioners, patients have been discharged as sane under their orders, who have been in a short time returned to confinement as confirmed and dangerous lunatics.

The proposed Bill, in addition to the highly dangerous and almost absolute power given to a Barrister, of ordering the discharge of lunatic patients, subject only to the approval of any medical practitioner, however inexperienced, whom he may call to his aid, contains other provisions, unnecessarily onerous as well as humiliating to the members of the medical profession, by authorising such Commissioner to write in a book, to be kept for the purpose at every lunatic asylum, whatever strictures or observations may suggest themselves to him on the conduct of the proprietors of such asylums, and by compelling such proprietors, under heavy

penalties, themselves to forward copies of such strictures and observations within three days, to the clerk of the Metropolitan Commissioners, although it is manifestly the duty of such Commissioner, or the clerk of the visitors, if there be any cause of complaint with regard to any lunatic asylum, to report the same to the Metropolitan Board, with the reasons on which it is founded, they being *paid* for the performance of their duty.

Although proprietors of lunatic asylums may be liable to actions for the escape of patients under their charge, yet the present Bill proposes to compel such proprietors, under a heavy penalty, themselves to furnish the evidence of such escape, by giving notice thereof, within two days, to the clerk of the Metropolitan Commissioners, the effect of which must necessarily be to induce such proprietors, however reluctantly, to increase, for their own protection, the restraint now exercised towards lunatic patients.

The Bill also proposes to give the Barrister Commissioner a power hitherto unheard of in this country, of holding a court of inquiry whenever he may see fit, in any lunatic asylum, and of compelling the attendance of witnesses before him under heavy penalties, and their examination on oath; whilst, against the decision of such barrister, however improper, no appeal is provided.

It is therefore respectfully submitted, that the provisions of this Bill are unnecessarily inquisitorial and unjust towards proprietors of lunatic asylums, inexpedient as regards the public, and injurious instead of beneficial to the particular class of persons whom they are intended to protect, and that they will tend to prevent the superior classes of the medical profession from embarking in an occupation in which they would be subjected to much unjust suspicion, and to such arbitrary interference in the discharge of their professional duties.

The best security which the lunatic patient can have is in the respectability, the intelligence, and the experience of those intrusted with the charge of lunatic asylums, aided by a well-regulated system of inspection; but the present Bill is calculated to produce effects the very contrary of those for which it is ostensibly intended to be enacted.

Under these circumstances it is earnestly sought that the said Bill may not pass into a law without a previous inquiry in a Select Committee, before which the parties aggrieved by its unusually harsh provisions might have an opportunity of being heard, and of tendering evidence in their defence.

*Mr. Wakley's Amendment.*—The House of Commons went into committee on the bill to which the above refers on the 20th, when it was moved by Mr. Wakley as an

amendment, "That two of the Commissioners to be appointed should not have their profession stated, and that their appointment should be left to the Lord Chancellor." This was opposed by the mover of the bill, Lord G. Somerset; but, we are happy to say, Mr. Wakley's amendment was carried. The farther proceeding in committee was then postponed till that day fortnight.

### MEDICAL REFORM.

*To the Editor of the Medical Gazette.*

SIR,

MAY I be permitted to make a few remarks on the subject of medical reform in connection with Sir James Graham's proposed Bill.

It may be presumed that any such measure must have for its object the welfare of the medical profession and that of the public community; but neither of these two great ends seems likely to be secured by the Bill in question. On the contrary, it is calculated to degrade the general practitioner in two ways: First, by not protecting him from the intrusion of uneducated and unlicensed persons, thereby ranking him in society and profession with the ignorant and unprincipled (for any man must be unprincipled who, without being qualified, undertakes the duties of the medical profession), and diminishing his prospect of that fair remuneration to which he is entitled after a laborious and expensive course of study;—second, by entrusting the examination of candidates to the College of Physicians, instead of allowing it to remain in the hands of the general practitioner, as it at present stands. Such an alteration would operate in two ways: it would be pronouncing the body of general practitioners unworthy of, or incompetent to discharge, the duties of so important an office; and it would at the same time be the means of depriving them of all future means of seeking the advancement of their own body in professional attainments and respectability. Are they unworthy of, or incompetent to undertake, so high a trust? Let the manner in which the Society of Apothecaries, for the last 25 years, have worked out their Act of Parliament afford an answer to that question. By gradually requiring a more extended education, and by instituting a higher style of examination, they have at length brought up their curriculum of study and test of examination to a degree of excellence admitted by all. The names of several gentlemen might be mentioned who, for years past, have been labouring in that field of usefulness, and have been aiming at the elevation of the character and education of the general practitioner. Such men, by their persevering labours in

such a cause (labours in great part unacknowledged and unseen by the public), have secured the diffusion of knowledge throughout the profession generally, which otherwise would have been confined to a few. But would it be the interest of the College of Physicians to follow in the same steps? In reply to this question I would beg leave to quote the following from the *MEDICAL GAZETTE* of last week:—"We more than fear that, in some quarters, the increased attainments of the general practitioner have been looked upon with feelings anything but kindly: it has been more than hinted that the apothecary must be pushed back from the dignified position which, by dint of hard labour and virtuous exertion, he has just (very justly) attained, in the expectation that, when that light is dimmed or extinguished, others may shine more brightly."

If this affected the general practitioner only, it might be of little comparative importance; but it affects the public as well as the whole profession. The forward movement in education began, as has been honestly stated, by one of the latest and most able writers on this subject, from the lowest grade of the profession: it impelled, and still continues to impel, the other bodies to continued exertion, in order to maintain their more elevated position; and we are convinced that the general practitioner cannot be degraded without damaging the reputation and influence of the profession at large. If this be true, and no one can deny it, would it be just to the general practitioner to take from him the means of maintaining and promoting the welfare of his own body, by transferring the duties of examination, and the regulation of the course of studies, to another body whose interest it would be to create a wide distinction between the two by the elevation of themselves at the cost of the other. It is a principle of justice, that every individual and every body of individuals should possess the means of self-improvement and advancement: but how is this important object to be effected by the large class of general practitioners, if they are not to possess within themselves the power of fixing on a high standard of education and examination to be submitted to by all who may wish to become members of their body? As Sir J. Graham's Bill is calculated to degrade the general practitioner, so also does it bid fair to be injurious to the public by not protecting them from the mal-practice of the ignorant. If any persons, whether licensed or not, be permitted to practise, the country will be overrun by the uneducated and needy adventurer, and no one can tell the extent of the evil. Instances of such mischief must be known to many. I have myself seen a patient in a fatal fit of apoplexy, with a number of leeches applied to the throat; the

practitioner who was called in having mistaken the stertorous breathing for that of croup. I have seen a contused thigh put up in splints for a fractured one; and I have known a woman in labour, with an arm presentation of the child and the hand protruding, left by the practitioner, saying that every thing was going on right, and that they must wait the result of more pains. But all these cases happened to the unlicensed and the uneducated who were in practice prior to 1815, and could not occur in the present day: yet they may occur; and such cases must frequently again occur, if the proposed Bill ever became law. In conclusion I would say, let the general practitioner protest against, and steadily resist, any measure that does not secure to him two things—protection against the unlicensed, and the regulation of his own body; or, in other words, the means of maintaining and advancing the education and general attainments of the great bulk of the medical profession.—I am, sir,

Your obedient servant,

A SURGEON AND APOTHECARY.

April 14, 1842.

### QUALIFICATION FOR "UNION DOCTORS."

*To the Editor of the Medical Gazette.*

SIR,

IN your leading article for the 15th instant, in the midst of an able and liberal commentary upon the new medical regulations of the Poor-law Commissioners, there occurs a passage from which it would appear that one important point in the Qualification Order has escaped you. "If," you say, "a practitioner possesses an English qualification as physician or apothecary, and a surgical one from Ireland or Scotland, they (the Commissioners) will allow him to be elected, on application from the guardians for that purpose." "This," you add, "seems right."

But on referring to the context, we find that this apparent liberality is extended only to cases of positive necessity; to cases where guardians cannot procure the services of a person possessing the double English qualification. In fact, wherever a medical man is forthcoming who has that qualification, the member of a Scotch or Irish College of Surgeons, even if also a licentiate of the Apothecaries' Company in London, is virtually disqualified, is publicly declared unfit to attend even the poor; and is thus indirectly marked out as being especially undeserving of the confidence and patronage of the paying classes. Surely, sir, you will not say that "this seems right." Fearful of

misinterpreting the article in question, a Member of the College of Surgeons, Edinburgh (and L.A.C.L.) wrote to the commissioners to inquire whether practitioners in his position were, by that article, admitted as eligible to Union office, *equally* with those who had the double English qualification, or only in cases of *necessity*. The answer was, a reference to the regulations and the explanatory letter accompanying them.

One point of real, but scanty and solitary liberality, does indeed appear. Medical officers, duly licensed to practise as medical men, and already employed by a Board of Guardians, may, with the consent of the commissioners, be retained in office. But if such practitioners, although heretofore in office, do not happen to be so at the present time, they are evidently incapable of re-election. And is it not preposterous that a person, whom the commissioners designate as one duly licensed to practise, and who, in the letter of explanation, is said to be viewed by them "as virtually possessing a double qualification," should, under any circumstances, while able-bodied and respectable, be excluded from pauper practice?

What is intended by these illiberal distinctions? Is it meant simply to declare that Scotch and Irish surgeons are illegal practitioners in England or Wales? or is it in prospect that the new order will compel such surgeons to take out a second diploma in London? If the former be the object of the commissioners, it is in the very teeth of the two Acts of Parliament which are cited in the appendix to the recently published list of the members of the London College. Those acts (relating to juries and the visiting of gaols) apply solely to England and Wales; and yet they expressly give equal immunities and privileges to the members of the three British Colleges of Surgeons. The legislature, in exempting members of the Edinburgh and Dublin Colleges from service as jurymen in England and Wales, acknowledges the legality of their practice in those divisions of the empire; and in affirming that they are eligible as surgical inspectors of gaols, with equal clearness admits their qualification and competency as surgeons.

And after the disclaimer from Mr. Guthrie of having had any part in the framing of the qualification rules, can we for a moment suppose that any selfish views on the part of his College have influenced the Commissioners? That gentleman's high-spirited language to the Committee on Medical Education and Practice in 1834, added to the liberal wishes professed in his exculpatory letter to Mr. Hovell, render any such supposition incredible.

The worthy President excuses himself for not having pressed "any further alteration,

at this moment, on the attention of the Poor-Law Commissioners," upon the plea that Sir James Graham's bill for the improvement of the medical profession, which he intended to introduce into Parliament this session, will, if carried into effect, settle the matter in a highly satisfactory manner. But it is now well known that there is great improbability of the bill being brought in this session. Are we, then, to suffer for a year, perhaps for many years, a grievance whose injustice is admitted by Mr. Guthrie, and, according to his showing, by one of the Poor-Law Commissioners; and this a new grievance, too, created by the Commissioners themselves? Are we to suffer this merely because the older grievances that weigh upon various classes in the profession cannot yet, conveniently, be redressed? We are content to bear the ills we have for any requisite time longer; but surely this is no time to burden us with new ones. It must, I think, be the feeling of every Scotch and Irish surgeon who is also an English apothecary, and who is disqualified for office in a Union by this new medical order, that the obnoxious article ought to be immediately modified by the Commissioners, or if they refuse, then even by Parliament itself.

Your insertion of the above remarks will confirm the rising character of your journal for liberality and justice, and will, I think, oblige many besides

Your very obedient servant,  
EDINBURGO-LONDINENSIS.

## MR. GUTHRIE AND THE UNION DOCTORS.

*To the Editor of the Medical Gazette.*

*Evans.* "Sir John, good worts."

*Falstaff.* "Good worts, good cabbage."

*Merry Wives of Windsor.*

SIR,

I AM one of a rather numerous class of the profession, who, for the most part, have looked on in silence, whilst much ink has been shed, and much breath expended, professedly with a view to our benefit. In a word, sir, I am a "Union Doctor," to use the happy and appropriate language of the President of the Royal College of Surgeons.

Referring to that gentleman's communication to Mr. Hovell, (is he also a "Union Doctor?") as published in the *MEDICAL GAZETTE* of March 27, I am ashamed to confess my belief, that in no case has there been a greater disproportion between the amount of benefit rendered to the cause advocated, and the self-complacency with which merit has been assumed for imaginary services. In truth, if it were for a moment possible to doubt the honesty and good faith of Mr. Guthrie's intentions, I should apply

to his labours the language of Troubridge, reporting to Nelson the services of his foreign allies—"that they had a diabolically good understanding with the enemy."

Mr. Guthrie's language is not always very clear, perhaps; but his general meaning is plain enough: viz. to convey an impression that the Poor Law Commissioners are very good fellows—perfect gentlemen, every inch of them; with the highest respect for, and best intentions towards the medical profession; and thwarted in their liberal views by those confounded Boards of Guardians, where all individual responsibility is lost, as a body readily adopts principles which each member may disavow at will.

Mr. Guthrie, if not an "old bird," is, at least, an "old soldier," and should not have been taken by the chaff in which he seems disposed to feast himself.

He asserts or admits that there is at present no security that Boards of Guardians generally will act up to their duty in ensuring (by adequate payment) the reality of proper medical attendance for the poor; and that this state of things is not likely to be changed, unless a principle of remuneration be laid down and enforced by the Poor Law Commissioners. Yet, strange to say, almost in the same breath, he confesses he could not press on Mr. G. Lewis, "consistently with that courtesy which is due to all public functionaries"—the inquiry whether the Poor Law Commissioners have the power of establishing a guiding principle of fair remuneration.

How amiably polite! I will venture to say that Mr. Lewis in return will give a high character to Mr. Guthrie; and, at the least, pronounce him a very agreeable person in his mode of transacting business with "public functionaries."

I am sorry to say, sir, that experience of what has taken place in my own part of the country, with observation and inquiry as to what passes elsewhere, have strongly impressed on my mind a view altogether opposed to Mr. Guthrie's. I believe that from the commencement of the commission, and in particular at the time when districts were formed and salaries fixed, none have done more to lower the estimate of medical services, by a uniform, though guarded tone of sneering depreciation, than the agents and representatives of the Board in London; I mean those well-paid and lightly-worked officials—the Assistant-Commissioners. With them I confidently assert (there may be individual exceptions) that "the guiding principle" generally adopted and recommended to Boards of Guardians, has been the rule, in this case most false and sophistical, "that a thing is worth what it will bring;" and consequently a reference to economy as the main object in fixing medical salaries: a rule

or principle, be it observed, not in the slightest degree affected by the promised abolition of tenders, the prevalent extent of which has been grossly over-rated, and has consequently been dwelt upon to the comparative neglect of points infinitely more important.

Be assured, sir, that if any real service is to be rendered to us poor devils of "Union Doctors," something more is required than fair words. "*Suaviter in modo*," if you please; but "*fortiter in re*" is indispensable. The attack must be made, not on out-posts, but on the key of the whole position.

Nothing can be more clear than that the Commissioners, if they were really in earnest on this point, might and would express an opinion as to the impossibility that justice can be done either to the poor or to the profession without an adequate rate of payment for medical services; and would instruct their subordinates to explain and enforce such views to Boards of Guardians.

Assistant Tithe Commissioners meet with no insuperable difficulties in adjusting the mutual or conflicting interests of tithe-owners and tithe-payers. How could an Assistant Poor Law Commissioner better deserve his £800 per annum than by being employed to perform a somewhat similar office, as between rate-payers, the poor, and the "Union Doctors?" Each district might then have a fair salary attached to it, on a due consideration of its size, population, character, &c.

These, sir, are mere truisms; and I repeat, that if the Poor Law Commissioners had been, or were now in earnest, they would not have failed to adopt a line of proceeding more obvious and familiar to them than to any other parties.

With these views, sir, you will not be surprised if I should fix a low estimate on the benefits likely to arise from Mr. Guthrie's suggestion, that the members of the profession should direct their efforts to "strengthen the hands" of the Poor Law Commissioners, so as to enable them, not only to declare the principle of remuneration they are pleased to adopt, but also to carry out and enforce its details in a satisfactory manner.

"Where there is a will there is a way;" the powers of those gentlemen are sufficiently cogent for most purposes; and if there were any doubt as to their extent with reference to this particular subject, I venture to assert, with confidence, that the faintest expression of a wish by them for an enlargement of those powers, would have received the unanimous support of all parties in parliament and out of it. They have not asked for anything of the sort; and it seems a just inference, either that they deem their powers, *quoad hoc*, sufficient; or that they do not care to ask for such as might throw on their

shoulders that responsibility for non-interference which they at present contrive to evade.

I may, with your permission, hereafter trouble you with a few comments on their late regulations, particularly with reference to the system of paying for operations, &c. "by the job," a practice originating in a system of generally inadequate remuneration, and, as I conceive, offensive and degrading as applied to the members of a liberal profession.—I am, sir,

Your obedient servant,  
A UNION DOCTOR.

April 6th, 1842.

## COLLEGE OF PHYSICIANS.

SENIOR AND JUNIOR FELLOWS.

*To the Editor of the Medical Gazette.*

SIR,

THERE is a suggestion in your number of last week respecting the title to be in future given to the *now* "Licentiates" of the College of Physicians, which, it strikes me, if acted on, cannot fail to give great satisfaction, and especially conciliate those desirous of joining the College. Perhaps the fact may be regarded as some evidence of my not being altogether free from the pettiness of our nature; nevertheless, I shall (under my mask) confess that one of the reasons which has prevented me from presenting myself for examination is the prospect of being written down "Licentiate." I never see the word without feeling that I should be assimilated to the respectable individuals "*licensed* to sell beer to be drunk on the premises." There is another precedent for the phrases, "Junior and Senior Fellows," proposed by your correspondent (besides those which he has mentioned), in the titles of members of the University of Dublin of different standing.—I am, sir,

Your obedient servant,  
M. D.

April 18, 1842.

## CIRCULATION IN THE BRAIN.

*To the Editor of the Medical Gazette.*

SIR,

WITH respect to the communication of Dr. Haworth, of Bolton, in last number of the MEDICAL GAZETTE, I would observe, that the experiments of Dr. Kellie, of Leith, prove that the circulation of the blood in the brain is completely exempt from atmospheric pressure, and that this pressure is not experienced, either directly or indirectly, in the brain "*whenever blood-vessels or nerves*

*escape from the skull,"* but only when a portion of the skull is actually removed. Such are the results of Dr. K.'s experiments. The views of Dr. Haworth, on the contrary, are founded on the supposition of atmospheric pressure being exercised on the whole mass of the brain, as well as upon its blood-vessels. This doctrine holds a very prominent place in both of his communications, particularly the concluding paragraphs of the last. Now such an opinion is so obviously opposed to the experiments alluded to, that to occupy your valuable space with any further remarks would be preposterous.

In conclusion, Mr. Editor, allow me to say, that my note to Dr. Haworth was penned in the most friendly spirit. However inconsistent his views may be with experimental observations, they are certainly very ingenious : my only object in noticing them publicly, was to prevent their assuming the position of facts. With regard to aeronauts not experiencing the sensations of vertigo, &c. &c., felt by those who ascend high mountains on foot, I never thought of calling in question this well-known fact, but cannot consent to the explanation of it given by Dr. H. The manner in which he *makes* Dr. Holland appear to confirm his views on this point, is certainly more commendable for its novelty than its philosophy.

I am, sir,

Your obedient servant,  
JOSEPH BELL.

Barrhead, April 14, 1842.

## SOFTENING OF THE HEART, WITH THINNING OF ITS PARIETES.

DR. STOKES said that the heart before him was taken from an individual whose case possessed more than ordinary interest, from the great doubt and difference of opinion to which it gave rise. He would detail briefly what he knew of the history of the case. It was an example of that class of affections which every practitioner must have met with at some time or other, in which the diagnosis remains obscure although most of the symptoms are of an important character. The case he was about to detail would furnish an example. An individual, who appears to be in good health, looks well, has a good appetite, is strong, able to take exercise, and to fulfil the duties of an active profession, applies for medical advice, and the only thing remarkable about him is a singularly irregular and rapid pulse, so quick and so deficient in regularity that it is almost impossible to count it. The action of the heart is also irregular and cannot be analyzed. Of this description of case Dr. Stokes said

that every practical man must have seen examples. Looking to the specimen before him it would be hard to define what was its exact pathological condition. The person from whom it was taken had the peculiarity of circulation, already mentioned, for several years. Some years since he left this country for a warm climate, and was at that period in perfect health. After residing there for seven or eight years, he was attacked with one of those affections incidental to warm climates, and consulted a military medical officer, who, having remarked the singular state of the circulation, was informed by the patient that he had noticed this condition a long time before ; soon after this he was invalided and sent home. He arrived in this country somewhat reduced in strength, but in a short time recovered, with the exception of some cough and difficulty of breathing. He consulted a very eminent medical man, who gave it as his opinion that it was a case of dislocation of the heart consequent on empyema of the left side. He then went to London, where a different opinion was given (the exact nature of which Dr. Stokes did not know), and after some time returned again to Dublin. When seen by Dr. Stokes he had the appearance of a man in good health. He complained of a cough and difficulty of breathing, particularly on making any active exertion, but stated that he could go about and enjoy society. There was one peculiarity in his case worthy of attention : he stated that he was always better when he took a free allowance of wine, and that abstinence or depleting medicines made him worse. He had no anasarca, nor was there any thing in his countenance expressive of disease of the heart. The pulse as before described, the action of the heart quick and irregular but feeble, and the sound on percussion over the præcordial region not remarkably dull. There was no evidence of effusion into the pleura, and his cough was merely a slight dry catarrh. Dr. Stokes recommended him to go down to the country, and remain there for some time. During his stay there he contracted a bad bronchitis, and let it run on for a week without using any remedy. He returned to Dublin, and when seen by Dr. Stokes he had violent bronchitis, with sonorous and wheezing rales anteriorly ; posteriorly in both lungs, towards the lower parts, an intense muco-crepitating rale was heard. The action of the heart now became more feeble and irregular, while the same rapid action continued ; and the pulse grew daily weaker and fainter, until it could no longer be felt at the wrist ; and his limbs became oedematous, blue, and cold. The impulse of the heart became gradually weaker and weaker, until at last it appeared to cease altogether. He remained

in this state for four days, and then died. Every kind of stimulant was employed with the view of rousing the action of the heart, but without effect. In one night he used a bottle of brandy, and a considerable quantity of wine. The misery he endured from an overwhelming sense of exhaustion appeared to be extreme; and as his voice, which was naturally strong, never failed him until a few moments before death, his outcries were truly heart-rending. The symptoms connected with the heart were, extreme irregularity, and extreme rapidity of action, absence of murmur, and very feeble impulse. On opening the thorax the heart appeared to be greatly enlarged; but this arose from the distension of the right ventricle and auricle, which were very much enlarged and filled with blood. There was no trace of inflammation anywhere. The right ventricle was thin, and appeared to contain more adipose substance than usual, but was not in the fatty condition described by Mr. Smith at a former meeting. The left ventricle was enlarged, but not thickened. The whole substance of the heart was softened; so much so, that it broke down readily under the finger; and in taking the organ out of the thorax, a rent occurred, passing from the posterior part of the right ventricle across the septum cordis. All the valves were healthy. Dr. Stokes observed that this case would throw some light on the general nature of the disease. There was one point to which he would allude briefly: Laennec states that clearness of sound in affections of the heart indicates dilated cavities; without denying this, Dr. Stokes would remark that clearness of sound indicated not merely dilatation of cavities or mechanical thinning, but also strong action of the muscular fibres of the organ; dilatation and thinning might occur without increased clearness of sound.—*Dublin Journal of Medical Science.*

LECTURES  
ON THE  
PRINCIPLES AND PRACTICE OF  
PHYSIC,

*Delivered at King's College, London,*

BY DR. WATSON.

*Dysentery. Diarrhœa adiposa. Intestinal concretions. Worms.*

ANOTHER of the morbid fluxes from the alimentary tube, of which I have yet to speak, is *dysentery*.

Its characteristic symptoms are, griping pains in the abdomen, followed by frequent, mucous or bloody stools, straining, and tenesmus. In chronic cases pus is sometimes discharged from the bowels. The acute form or stage of the disease is attended with fever.

The differences between dysentery and diarrhœa are obvious enough. Both of them may be accompanied by griping pains: in both the stools are frequent and loose: but in diarrhœa they are fecal; in dysentery there is retention of the natural feces, or they are expelled, from time to time, in small, hard, separate lumps, termed *scybalæ*. Again, straining, and tenesmus, and the excretion of mucus, which is often tinged with blood, form no necessary features in diarrhœa; whereas in dysentery these symptoms are prominent and constant. These nosological distinctions are true and useful, although in our actual intercourse with the sick we do not find them always or strictly observed. Some of the worst forms of dysentery commence with the ordinary symptoms of diarrhœa.

Dysentery consists, essentially, in inflammation of the mucous membrane of the large intestines; yet not, I apprehend, of the whole of that long surface indiscrimi-

nately. Observation of the course of the disorder during life, and of the morbid appearances visible after death, leads to the conclusion that in simple dysentery, marked by tormina and tenesmus, and frequent dejections of sanguinolent mucus without fecal matter, the inflammation chiefly affects the *rectum* and the *descending colon*. When the earlier portions of the large intestine are involved in the diseased process, the stools at the outset are often composed in great measure of excrement in an unnaturally fluid state, and mingled with blood and slime. We generally speak of these circumstances as constituting *dysenteric diarrhœa*.

Slight and simple dysentery may occur and run its course with very little or no disturbance of the circulation. When it is acute and severe, it is attended with more or less pyrexia. The acute disease may terminate in recovery; or in early death; or in chronic dysentery, which usually, in the end, is fatal.

The wards of our metropolitan hospitals bring frequently under our notice severe cases of chronic dysentery in the persons of soldiers and sailors, who bring the disease home with them from hot climates. With these exceptions, dysentery is, now-a-days, neither a very common nor a very serious disorder in this country. I say now-a-days, for the time was when it raged in London like a plague. The present Dr. Heberden, in his valuable essay, *On the Increase and Decrease of different Diseases*, shews, that in the 17th century the number of deaths set down, in the weekly bills of mortality, under the titles *bloody flux*, and *griping in the guts*, were never less than 1,000 annually, and in some years exceeded 4,000. For five and twenty years together, viz., from 1667 to 1692, they every year amounted to above 2,000. During the last century, the number gradually dwindled down to 20. Dysentery is one of the pests of hot climates. In all tropical regions at certain seasons of the year it is very prevalent and

destructive. But it is in fleets and armies, and especially among troops in actual service, that the distemper most displays its terrible power. There is no single malady which is so crippling to an army in the field as this. Sir James M'Grigor, to whom was entrusted the superintendence of the medical department of the army "on the two greatest services on which the military force of this country has, of late years, been employed, namely that in Walcheren, and that in the Peninsula," calls dysentery "the scourge of armies," and "the most fatal of all" their diseases. In two years and a half, the British army in Spain lost no less than 4717 men by this complaint.

How are these facts to be explained? Wherefore is dysentery, which was so familiar to our ancestors, so happily rare among us? Why does it thus wait upon and afflict the march of armies? Upon what depends its frequency in hot climates? We may expect to obtain some answer to these questions by searching into the *causes* of the disorder.

It has been ascribed to exposure to wet and cold; to the use of unwholesome food; to the agency of malaria; to contagion.

Weather and season have a manifest influence in the production of dysentery. In temperate climates, like our own, it is an autumnal disorder. In tropical countries it is observed to be more common and more severe when rains succeed to long-continued drought. In respect to this, as to other bowel affections, a high diurnal temperature of the air appears to be the predisposing, and exposure to cold the exciting cause. I stated, on a former occasion, that great vicissitudes of temperature are very frequent and very pernicious, even under the torrid zone. Scorching days are followed by extremely cold nights. The dysentery which arises under these circumstances is apt to run on into the ensuing winter. Soldiers in the field against an enemy are peculiarly obnoxious to the agencies which favour or generate the complaint. Marching, or engaged in actual conflict, during the day; bivouacking at night, often in the open air, and under every variety of weather; ill-provided too often with clothes and bedding; their food scanty, precarious, or of bad quality; seizing the many opportunities which their dreadful trade supplies of license and intemperance; depressed, it may be, by disaster or defeat; we need not wonder either at the prevalence of dysentery among them, or at its untractableness while they remain subject to the same morbid influences. Neither can the causes be warded off from the patient, nor, in general, can the patient be removed from the causes. Yet occasions do arise which show distinctly enough this alleged relation of cause and effect. *Præsens*

*morbum facit—sublata tollit.* Take, on the one side, the following facts from Sir John Pringle's book *On the diseases of the army*. The men who had fought at Dettingen lay that night on the field of battle, without tents, exposed to a heavy rain. For the next night or two they encamped on better, but still wet ground; and they wanted straw. Nearly half of these troops were soon after affected with dysentery; while three companies which had not been engaged in the battle, nor exposed to rain, nor lain wet, escaped the complaint entirely. Take this converse fact, related by Desgenettes. Four hundred of the French "army of Egypt," reduced to a state of extreme weakness and emaciation by dysentery there contracted, embarked at Alexandria on their return towards France; were carried away, in short, from the alleged causes of their disorder. Nineteen died at the very outset of the voyage; which had, however, so good an effect upon all the rest, that before they reached Malta they were thoroughly convalescent.

The very frequent coincidence or alternation, in some places, of dysentery with intermittent fever, has given rise to the opinion that both these diseases are alike attributable to the malarious poison. But dysentery prevails where there is no other evidence of the presence of malaria. You may recollect that when we were upon the subject of ague, I showed you that its repeated paroxysms were attended with extreme and increasing congestion of blood in the internal organs; of which congestion the tumid spleen, the ague-cake, was an effect and a token. Now whatever gorges the splenic vein, gorges its tributary, the inferior mesenteric, which carries the blood from the rectum and the descending colon. Upon such congestion of the mucous membrane inflammation is readily engrafted; and in this indirect way dysentery may be said to result from the marsh effluvia. Ague is an effect of malaria; and dysentery is, sometimes, a sequela of ague. In precisely the same manner, dysentery is apt to supervene, in hot climates especially, upon hepatic congestion and disease.

That dysentery is, in itself, a *contagious* malady, we have no satisfactory evidence. In its sporadic form, in this country, we never see it spread from person to person. But it is a prominent symptom in some epidemic visitations of continued fever, which undoubtedly is contagious. To this fact I am inclined to attribute the notion, formerly much more common than it now is, that simple dysentery is catching.

The remarkable decline of dysentery in this metropolis has been contemporary with that of other severe disorders; and is due to the same combination of causes. For nearly

two centuries we have had no *plague* among us. *Agues*, formerly very rife in London, have almost disappeared. *Continued fevers*, which used to break out annually in hot weather, are comparatively unfrequent. I believe that we may trace these great blessings to an event which was regarded, at the time, as a national judgment; I mean the great fire that, in 1666, consumed every thing between Temple Bar and the Tower. The streets and houses thus destroyed had been filthy in the extreme, close, densely crowded, and consequently most unhealthy. The impurity of the air excited, perhaps, some complaints; and it certainly predisposed those who dwelt in it to various kinds of disease, "the seeds of which (says Dr. Heberden) like those of vegetables, will only spring up and thrive when they fall upon a soil convenient for their growth." To the better construction of the houses and of the streets in the rebuilt city; to the increased means of ventilation; to the general formation of drains and sewers; to the more copious supply of water; and to the more temperate and cleanly habits of the people, we may fairly ascribe our present exemption from dysentery, from ague and continued fever, which are often the parents of dysentery, and from the plague itself. In many parts of this overgrown place there is still much room for improvement.

The pyrexia that accompanies dysentery sometimes begins before the local symptoms declare themselves; more frequently it succeeds their manifestation. Occasionally the fever runs high, the pulse is hard and frequent, the skin hot, the face flushed, and the tongue furred; and the patient complains of headache and thirst. But in this, as in other abdominal diseases, the pulse soon becomes small and weak, the strength rapidly declines, and the temperature of the body sinks.

In acute cases the pain is often severe; but it is subject to remissions and exacerbations. It occupies the hypogastrium, or some part of the course of the colon, where there is usually more or less tenderness on pressure. The patient is tormented by a sensation as if there was some excrement ready to be dislodged; goes perpetually to the night-chair, and is irresistibly impelled to strain violently to get rid of the irritation. But the efforts are ineffectual; he discharges but little; and what is voided is either altogether a jelly-like mucus (in which case the complaint has been called the *dysenteria alba*, and the *morbus mucosus*), or more commonly it is mucous and bloody (the *bloody flux* of our old authors), mixed with films and membranous shreds. In many of the dejections there is no genuine fecal matter at all; or the small indurated balls which I just now mentioned come away occasionally.

Frequently the ejected mucus is variegated in colour, green, or black, or reddish, like the washings of meat, and horribly foetid. Sometimes pain and difficulty in making water are added; there is *dysuria*, the irritation of the rectum being reflected upon the bladder through the lower portion of the spinal cord. Sometimes the stomach sympathizes, and nausea and vomiting ensue. With all this local suffering there is a continuance of febrile distress; the patient passes sleepless, or dreamy and disturbed nights, and is low-spirited and desponding. In the fatal cases the pulse becomes very small and rapid, the features sharpen, and the surface grows cold. Death begins at the heart.

Inspection of the dead body discloses more or less ulceration, chiefly of the large intestine. The glands that are scattered over its surface are enlarged and prominent, looking somewhat like small-pox pustules, for which indeed they have been mistaken. They probably form the foci of most of the ulcers, which are sometimes narrow and oblong, lying across the gut; sometimes very large and irregular, with here and there islands or ridges of thickened mucous membrane. In the worst cases the whole extent and circumference of the bowel presents one irregular, confused, and tattered mass of disorganization.

When submitted to early *treatment*, and when its exciting causes can be averted, or avoided, dysentery is not an intractable disorder. Sir James M'Grigor remarks of the camp dysentery in the Peninsula, that it had two stages, which it was of consequence to note, because they required different and almost opposite modes of treatment: the inflammatory stage, and the stage of ulceration. A plan proposed by Dr. Somers appeared to Sir James so judicious, and proved so successful, in the first attacks of the pure unmixed disease, that he recommended its general adoption in the army. It was this.

First, the patient was freely bled. Immediately afterwards twelve grains of Dover's powder were administered. This dose was repeated three times, at intervals of one hour. Plenty of warm barley-water was at the same time given, and profuse sweating encouraged for six or eight hours. A pill, containing three grains of calomel and one of opium, was exhibited every second night; and in the intervening day two drachms of Epsom salts dissolved in a quart of light broth. The venesection was repeated, while the strength and the pulse permitted it, until the stools were free or nearly free from blood; and Dover's powder, as a sudorific, was always given after the blood-letting. When the pains were great, and attended with much tenesmus, the warm bath gave instantaneous relief. "This plan being

steadily persevered in for a few days, the inflammatory diathesis of the intestinal canal, which had excited symptomatic fever throughout the general system, was found gradually to yield, and make way for returning health."

If the disease was not cut short by this method, but advanced into the second stage, and became chronic, the most effectual remedies appeared to be laxatives, and opiates, given alternately; and combined with such medicines as promote perspiration. The abdomen should be swathed with flannel, or covered by a warm adhesive plaster. Much benefit may be obtained from the employment of clysters, if there be not too much tenesmus to admit of the introduction of the pipe of the injecting syringe. Warm starch, with laudanum in it—not exceeding in quantity a couple of ounces, lest the irritable bowel should expel it again—will sometimes afford signal relief. Or if the pain and tenesmus are so great that a clyster-pipe cannot be used—or the enema is not retained—a grain or two of solid opium inserted into the rectum, beyond the sphincter ani, will often allay the distress. The food should be farinaceous and simple; and great care must be taken during the convalescence to prevent a return to improper diet, and a fresh exposure to cold.

There is one important point in the treatment of dysentery, concerning which a striking discrepancy of opinion exists, even amongst practitioners who have had large experience of the disease: I allude to the employment of mercury as a remedy. I have no data for settling the question: but the amount of evidence appears to be against its indiscriminate use. It seems (as we might expect) to be powerful both for good and for evil. Sir James M'Grigor has probably hit the distinction which should guide us to prescribe or to withhold this drug. It was, he tells us, when the dysentery was complicated with disease or disorder of the liver, that mercury proved so highly useful: when along with the dysenteric symptoms there were present a dull pain in the hepatic region, and in the right shoulder, a yellowish brown colour of the skin, and of the conjunctiva, and uneasiness when the patient lay in any other posture than on the right side. He adds: "In the early stage of the acute and unmixed disease, and before venesection has been performed, mercury will aggravate the symptoms. In the more advanced stage of the disease, particularly when there is hectic fever, with extensive erosion or ulceration of the intestine, it is invariably found to hurry it on to a fatal termination."

The sporadic dysentery which we chiefly see in this country seldom requires the lancet. Leeches, however, are to be applied, in the track of the colon, wherever there is much

tenderness on pressure. A full dose of castor oil may then be given; and after that an opiate. It is the practice of some physicians to prescribe laxatives and opium together; but in this complaint it is better to alternate them. Opiate enemata are of service for relieving tenesmus. These remedies will be much assisted by the warm bath; by hot fomentations to the abdomen; and by such means as promote the natural secretions of the skin. If there be any reason to suspect that the portal system is gorged with blood, complete relief to the dysenteric symptoms may often be obtained by the practice which I recommended as proper in melœna; viz. the exhibition of five grains of calomel at bed-time, and of a senna draught the next morning, for two or three days in succession. Should the symptoms still drag on, it may be necessary to give mercury, even to the extent of making the gums tender; but it should be introduced gradually. Equal parts of *hydrargyrum cum creta* and of *Dover's powder*, constitute a very good combination either in pill or powder for such forms of the complaint. But in the milder cases of simple sporadic dysentery there is no occasion, I had almost said there is no excuse, for giving your patient a sore mouth by the lavish employment of mercurial remedies.

The fluxes of which I have hitherto spoken have all consisted in an immoderate discharge of some of the usual contents or secretions of the alimentary tube, in an altered and unnatural state. But matters are sometimes voided from the bowels totally unlike any of the healthy discharges. *Adeps* is not an intestinal excretion; yet it is sometimes passed, in great abundance, by stool. Many unquestionable instances of this are on record, both in ancient and in modern literature. Though I have never met with one, and therefore have but little to say on the subject, I must not pass it over altogether. A certain quantity, sometimes it has been a large quantity, of oil, of liquid fat, has been poured forth, in a sort of diarrhoea. Sauvages was aware of this disorder, and calls it, in his Nosology, *diarrhœa adiposa*. In a paper in the *Medico-Chirurgical Transactions* upon this subject, Dr. Elliotson refers to an example of it described by Tulpius, in which a woman discharged every day for fourteen months a considerable quantity of yellow fat, that lay upon the fœces like melted butter. When voided into a vessel of water it floated, like oil, upon the surface; and when cold it assumed the consistence and appearance of fat. Like fat, it was very inflammable, and burned with a bright flame. With all this there was no kind of distress, nor any wasting of the body: and the patient was in excellent health sixteen years afterwards. Dr.

Elliotson had a case of this kind under his own care. The man had also diabetes and phthisis. The symptoms were precisely the same as those described by Tulp. Dr. Prout and Dr. Faraday analyzed portions of the adipous matter, and they pronounced it to be genuine fat. Mr. Lloyd, of St. Bartholomew's Hospital, has given us the details of a case in which the evacuation of grease was associated with jaundice. The excretion looked like melted fat, but when cool had the consistence of butter. It swam on the surface of water, melted at a moderate heat, and burned readily. In this instance the head of the pancreas, and the duodenum, were involved in a mass of scirrhus disease. And this is a very curious fact: for Dr. Bright also states that in three different persons, each of whom he had known to pass fat from the bowels during life, and whose bodies he had had the opportunity of examining after death, he found scirrhus disease of the pancreas, and fungous disorganization of the duodenum.

The remarkable coincidence occurring so often of these fatty discharges with cancerous disease of the pancreas and duodenum, is well worthy of being borne in mind; although it may not, as yet, afford any explanation of the phenomenon.

All that we know of the disease seems to amount to this: that it is not a *common* complaint; and that it is not necessarily a *fatal* complaint: for persons who have passed great quantities of fat in that way have lived in good health for many years afterwards. Yet though not *necessarily* fatal, it has frequently been found associated with incurable malignant disease in the duodenum and pancreas. Dr. Prout also informs us that in cases in which a similar oily fluid has been passed through the *urethra*, the *kidneys* have been found in a state of organic malignant disease.

With respect to the treatment of such cases, all the hints I can give you are such as are furnished by the two following facts:—

Mr. Howship, in his book on morbid anatomy, mentions the instance of a lady who was affected with this diarrhoea adiposa, and parted with vast quantities of fat; and who was cured upon the principle of *similia similibus curantur*, for she recovered after swallowing a pint of sweet oil. And Dr. Elliotson, acting on this hint, gave *his* patient, who was labouring at the same time under diabetes, a quarter of a pint of olive oil; and the voiding of fat greatly diminished from that time, and soon ceased entirely.

Whether these were really cures, or whether they were coincidences, is a question which we want larger experience to help us to determine.

When I was speaking of the causes of enteritis, I adverted to the presence of *foreign substances*, as they are called, in the bowels, and to *intestinal concretions*.

There are some points connected with these subjects which I had not then leisure to mention, but which you ought not to be ignorant of.

Intestinal concretions are very common in some of the lower animals—in horses and oxen especially. Most of you have seen, I dare say, immense intestinal calculi of this kind, and great numbers of them, in the museum of the College of Surgeons. The old remedies called *bezoars* were of the same nature.

They occur also, these intestinal calculi, in the human entrails, and in various parts of them; chiefly, however, in the cæcum and large intestines, but sometimes in the stomach: indeed, very large ones have occasionally been met with in the latter organ. Bonetus describes one which weighed nine ounces, and was as big as a hen's egg. Generally they are few in number in the same person; one only, perhaps, exists, or two or three. Yet as many as thirty have been found together in the stomach in one case; and in another case nine. One of the Monros of Edinburgh (Monro primus) detected twelve in the colon of a boy, during life, by the touch. Monro secundus took a concretion that weighed four pounds from the colon of a woman. They have been known to measure as much as eight inches in circumference. In the 24th volume of the *Edinburgh Medical and Surgical Journal* is an account of one long one, or, perhaps, of three that had become united together, weighing twelve ounces. Mr. Turner, of Keith, has very lately published the case of a man who passed fourteen large intestinal concretions.

Now what are these substances, and how do they get there? What is the pathology of the malady? Why, they seem to be formed, in many instances, by the deposit of saline particles, intermixed with animal matter, upon and around some accidental nucleus which has entered the alimentary canal, and stopped there. Sometimes a gall-stone forms the nucleus: the centre of the calculus has several times been found to consist of pure cholesterine. Those matters over which the gastric juice has no power, and which pass the pylorus unchanged—such as the stones of fruit, husks of grain, many unbroken seeds, portions of bone, and the like. Other of these intestinal concretions are evidently composed of a mass of short fibres, matted, or interwoven together, after the manner of *felt*. These calculi have a somewhat soft and velvety feel, yet are too hard to be much compressed. Sometimes they involve a nucleus, and

sometimes they do not. Their composition has been discovered in rather a curious manner. Mr. Clift, who, as you know, has long had the main charge of the Hunterian Museum, after attentively examining some of the specimens there collected, fancied that they might be formed somehow of the beards of oats; and the late Dr. Wollaston, at Mr. Clift's suggestion I believe, undertook to analyze them somewhat more rigidly; and he found that Mr. Clift's conjecture was well founded. If you have ever looked closely into the structure of an oat, which has been separated from its husk, you may have noticed that one end of it is formed somewhat like a tiny brush; made up of very minute needles or beards. Dr. Wollaston found that these ends were identical in their shape and composition with the fibres of the intestinal concretions.

The accuracy of the result of this analysis is singularly confirmed by the fact that this particular kind of intestinal calculus is almost peculiar to the bowels of Scotch people; among whom, as you know, oats form a very common article of diet, in the shape of *oatmeal*.

Concretions of the same species have also been found in the intestines of Lancashire persons; and they also use oatmeal a good deal as food. Mr. Children gives an account of some in the Philosophical Transactions for 1822. The fibres were cemented together by mucus; and the concretions contained also albumen, phosphate of lime and soda, and common salt.

I mentioned formerly the danger which attends the incautious or excessive use of magnesia, whether for stomach complaints or for urinary disorders. When this substance is taken habitually, or when due care is not taken to ensure its habitual expulsion from the intestines, it is liable to accumulate and concrete there, especially in the cæcum and colon. Large masses of this kind have been met with, composed almost entirely of carbonate of magnesia.

And the habitual use of any other indigestible substance may have the same ill consequence. The seeds of figs; unbruised mustard seeds, which (as I mentioned before) are taken daily by some persons; the woody knots found in certain pears; all these have been known to form the material of concretions, or of hard injurious masses in the bowels.

Now concretions of this kind come at length to produce symptoms by the pressure and distension they occasion, by the ulceration to which they sometimes give rise, and, above all, by the obstacle they oppose to the passage of the contents of the intestines. They generally cut the patient off by giving rise to inflammation.

But they may exist for a long time with-

out producing any definite symptoms. And when symptoms do arise, or when we ascertain that such concretions have formed, we are often at a loss for a remedy. From the *colon* we may hope at last to dislodge them: by mechanical means when they are near the outlet; by frequent injections of warm water, or soap and water, by which they may be softened or broken down, and washed out, when they are beyond the reach of the finger, or of instruments passed into the rectum.

We have an illustration of the patience of the alimentary canal under the presence of these masses, in what often happens when foreign bodies of some magnitude are swallowed and remain in the tube.

In one of the earlier volumes of the *Medico-Chirurgical Transactions* you may read the history of a celebrated knife-eater. A sailor, in a drunken bravado, swallowed a clasp-knife. This was followed by no immediate bad consequences, and he used to brag of the feat he had performed. And afterwards, either to satisfy the scruples of those who did not believe his assertions, or for the sake of rewards which some people were thoughtless and cruel enough to offer, or to win wagers, he stupidly repeated his folly, till he had swallowed (I think) thirteen knives of various kinds and sizes. They killed him at last; and their remains were found in various parts of the alimentary tract. But he had no serious symptoms for some time.

Mr. Wakefield has given us an account of a culprit, confined in the Cold Bath Fields Prison, who had swallowed seven half-crowns before his incarceration. One day out they all clattered into the pan of his night-chair.

I saw a prisoner myself, last autumn, in the Penitentiary, who, after some sickness, and tenderness of the belly, voided a half-crown from the rectum. This was in November, 1839. He had swallowed the piece of money two years and a half before—viz. in March, 1837; and, until within a week of his passing it, he had enjoyed excellent health.

Before I proceed to any of the other viscera of the abdomen, I may as well take such notice as the nature and limits of these lectures admit and require of the subject of *worms*: in which subject the intestinal canal is more concerned than any other part of the body. It seems a strange, as it is a somewhat humiliating fact, that the human body should furnish food and a habitation for many of the inferior creatures; not only after death, but while it is yet alive. The parasitic animals which thus prey upon man have been much studied from time to time, and especially of late, in their relations to natural history: and some of the facts that have been ascertained respecting them you

ought to be acquainted with. But I shall pursue the subject no farther in this place than it concerns us as pathologists and physicians. Its natural history will, no doubt, be fully taught you by the professor of comparative anatomy.

First, then, it is a notorious fact that numerous parasites do crawl over our surface, burrow beneath our skin, nestle in our entrails, and riot, and propagate their kind, in every corner of our frame: producing oftentimes such molestation and disturbance as require the interference of medicine. Nearly a score of animals belonging to the interior of the human body have been already discovered and described: and scarcely a tissue or an organ but is occasionally profaned by their inroads. Each, also, has its special or its favourite domicile. One species of *strongyle* chooses the heart for its dwelling-place, another inhabits the arteries, a third the kidney. Myriads of minute worms lie coiled up in the voluntary muscles, or in the cellular tissue that connects the muscular fibres. The *guinea-worm* and the *chigoe* bore through the skin, and reside in the subjacent reticular membrane. *Hydatids* infest various parts of the body, but especially the liver and the brain. A little *fluke*, in general appearance much like a miniature flounder, lives, steeped in gall, in the biliary vessels. Even the eye has its living inmates. But it is, I repeat, in the alimentary tube that we are most apt to be plagued with these vermin.

Independently of minute scientific divisions into genera and species, there are some broad lines of distinction between these creatures. Thus some kinds of worms occupy, as I have said, the interior of our bodies; these are called accordingly *entozoa*: some dwell externally, and are named *ectozoa*.

There are five sorts of intestinal worms, sufficiently common to make it likely that you will meet with some or most of them in your future practice. I shall, on that account, direct your attention first of all to them.

1. A frequent tenant of the human intestines is the round worm, so like in shape, size, and general appearance to the common earth-worm. It is from this species, no doubt, that the whole class are called *worms*. This round worm is often denominated a *lumbricus*; but that is erroneous: it is a species of *ascaris*, and it has been named by naturalists the *ascaris lumbricoides*—the *ascaris* that is like a *lumbricus*.

2. The *ascaris vermicularis*; or the *aryuris vermicularis*. These animals resemble slender maggots rather than worms. They are often called simply *ascarides*: or, in the vernacular, *thread-worms*: and they are very much like bits of white thread.

3. The *tricocephalus dispar*; also a small

worm, but longer than the last; its vulgar denomination is accordingly the *long thread-worm*.

4 and 5. Two species of *tania*; long, flat, articulated animals, resembling pieces of tape. The *tania solium*, or common tape-worm of this country; and the *tania lata*, or broad tape-worm.

Of all these I proceed to mention a few more particulars.

The *ascaris lumbricoides*, or round worm, is, I say, very like the common earth-worm, and used to be thought identical with it. It runs from five or six inches to about a foot in length, and it is of a reddish-brown colour, with a tinge of yellow. The female worm (for they are of both sexes) is much more common than the male, which is smaller also, and may be distinguished by a curved state of its tail, and by the genital organs. Sometimes young ones are met with, about an inch and a half long.

I shall not go into any minute description of the anatomy of these worms. You cannot mistake them, except for earth-worms; and the points of distinction between the two, when known, are easily perceived. The earth-worm, then, is redder than the intestinal worm, and less pointed at its two ends. The mouths of the two differ much; that of the earth-worm is a short longitudinal fissure, or slit, placed on the under surface of its small rounded head. In the *ascaris lumbricoides*, the mouth is situated at the extremity of the worm, is of triangular shape, and is surrounded by three tubercles.

It is curious that similar differences, only reversed, exist in respect to the other aperture of the alimentary canal, the anus. In the earth-worm this is terminal, at the very end of the cylinder: in the *ascaris* it is a transverse slit *near* the extremity, and on the under surface of the animal.

Again, the earth-worm has rows of little projections, like bristles, upon its under surface; feet they may be called, for they appear to serve the purposes of locomotion. In the parasite there is nothing resembling this.

By attending to these plain marks, you may avoid being deceived by impostors, who pretend that they are afflicted with worms, and to prove their case bring you an earth-worm or two in a bottle.

The *habitat* of these worms is in the small intestines. They may, and do, pass upwards into the stomach, or downwards into the large bowel: in either case they are generally soon voided. Sometimes they are vomited up: but they have been known to creep into the oesophagus, and thence into the nostrils. Andral states that he saw a case in which a child was strangled by one of these worms, which had turned back and become entangled

in the larynx. They have been found also in the excretory ducts of the liver. This Andral has witnessed; as has also Dr. Baron in this country.

It was formerly thought that these animals were capable of perforating the coats of the intestine: but that opinion is now generally exploded. They do not appear to have the means, if they possess the inclination, to bore through. What gave rise to this notion was the circumstance of their sometimes passing out of the bowel, through ulcerated or other openings, into the peritoneal sac; or into the vagina or bladder; or outwards through hernial apertures.

The number of these worms existing at the same time in the same person is very variable. The late Dr. Hooper mentions a child, eight years old, a girl, who voided upwards of 200 in the course of one week. An instance is recorded of a soldier who passed 367 in six days. Another patient got rid of 460 in a fortnight.

Fifty or sixty have been found in the same dead body. They often lie in packets. The corresponding portion of mucous membrane has in some cases been red, in others quite natural. Sometimes two are met with; sometimes one only. So that we cannot infer with certainty that because one such worm has been voided, more remain behind; although that is always probable.

This worm is more common in the early periods of life than afterwards.

The other species of ascaris, the *ascaris vermicularis* or thread-worm, resembles the former in some respects, but differs from it remarkably in size. Here also the female is longer and larger than the male; the one being perhaps half an inch in length, the other not two lines, and very slender.

The thread-worms live principally in the rectum, and sometimes exist there in vast numbers; thousands: and they pass out, or are ejected, matted together with mucus, in the shape of balls, or entangled in portions of excrement. Sometimes they emerge of their own accord, and crawl about the neighbourhood, getting into the vagina in females, and even into the urethra, and causing intolerable irritation, itching, and distress.

They are seen, when recently expelled, to be very lively; moving their anterior extremity about continually. From this restlessness and activity the name of ascaris is said to be derived—from the Greek word *ασκαρίζειν*, to leap.

This worm also belongs chiefly to infancy and childhood. It does sometimes infest adults; but generally as the patient grows older the animals cease to trouble him, whether curative means are employed or not. Bremser, however, knew a person 80 years old, who was nearly killed by them.

The third kind of these round worms is the *long thread worm*; the *tricocephalus dispar*. It is from an inch and a half to two inches long. One extremity, that to which the head belongs, is extremely fine and small; and then suddenly bulges out into a thicker body. The thinner portion is about twice as long as the thicker. Its name is derived from this variation of size. *τριξ*, a hair, and *κεφαλη*, the head; the portion to which the head is appended being as fine as a hair. At one time the head was mistaken for the tail, and then the animal was called *tricusis*, from *τριξ*, and *ουρα*, the tail. The thicker or body part is rolled up in a spiral form, especially in the male, the female being straighter. This worm is of a white colour, unless tinged by its food. It also affects the large intestine as its place of abode; but the opposite end of that gut, the cæcum, is its favourite spot. It is sometimes met with in great numbers, attached to the mucous membrane by its head; the body hanging loose.

Although generally overlooked, it is said to be extremely common, and to occur in most bodies. I have seldom seen it; but then I have never hunted for it. It infests the dog, the fox, the monkey, and other mammiferæ.

This species of entozoon attracted a good deal of attention about 70 or 80 years ago; it being then first observed in Germany during the prevalence of an epidemic fever, which was characterized by profuse mucous diarrhoea. Roederer and Wagler have given an excellent account of this disorder, under the title of *morbis mucosus*. It was thought to have been excited by these worms, which were found in abundance in the cæcum after death. This opinion must have been erroneous, for the animals were known, in other places, long before; and they produce, in general, no inconvenience.

The two *tæniæ* are more formidable beasts. With a general resemblance between them, there are strong particular distinctions.

The *tænia solium*, or common tape-worm, has a minute hemispherical head, and a long flat body, of a whitish colour, composed of many pieces curiously articulated together. The articulated pieces are quadrilateral, very short and small in the creature's neck; become gradually square as the distance from its head increases; and at length are longitudinally oblong. These portions, or *joints* as they are called, have foramina on their margins, leading to ovaries within. The foramina, which are very conspicuous, are placed alternately on the one side of the animal and on the other: on the right edge of one joint, on the left of that next to it. This arrangement is, however, subject to occasional irregularities. Each joint is let

in, as it were, to that immediately in front of it; and the connection between them is not very firm. It is less firm in proportion as the animal is older, and as we approach its posterior extremity: so that the segments are apt to come away, by stool, separately. They have somewhat the appearance of the seeds of cucumbers or gourds; and the parasites, for that reason, are sometimes called *cucurbitine* worms. Blumenbach and others have supposed that each articulated piece was a distinct worm: but that is not the case. The head of the animal, and its peculiar terminal segment, forbid this belief.

The common tapeworm is very narrow and thin towards its anterior extremity; one-third or one-quarter of a line perhaps in breadth. At its broadest part it may be from three to six lines wide.

The young *tæniæ* seem to be merely wrinkled; but they are really articulated. The question has been started, whether the lost joints are ever reproduced. It is believed that no new joints are formed, but that the original ones are gradually more and more developed. The animal is androgynous and hermaphrodite.

Specimens of this worm are preserved, upwards of 20 feet in length. Much exaggeration seems to have existed formerly about its size. It has been said to measure 150, and even 300 feet. In all probability separate portions of several have been estimated as forming parts of one and the same worm. There is one case well authenticated (it is cited by Bremser from Robin) in which a tapeworm was found to extend from the pylorus to within seven inches of the anus; adhering firmly to the mucous membrane all the way. The animal has the power of motion. Its movements are felt by the patients, within them; when recently expelled, and placed in tepid water, it may be seen to shorten itself; nay, portions protruding many feet from the anus have been known to draw themselves back again.

This kind of worm is more frequent in adults than in children: yet it is sometimes met with even in the foetus. It is exceedingly common in dogs. It has been badly named *ver solitaire*, for it is not always single. It is not only found in company with different worms, but also with others of its own species. Its natural place of abode is the small intestines: but it extends sometimes into the large, and sometimes into the stomach. Vandoverer declares that after an emetic one of his patients vomited forty Dutch ells of the worm, and might have got rid of more "if he had not been afraid of puking out all his guts, and for that reason bit the worm off."

The *tænia lata*, or broad tapeworm, has often been confounded with the *tænia solium*; yet there are striking differences between them; respecting which, for all prac-

tical purposes, it is enough to say that the heads (as viewed through a microscope) are very dissimilar; that the joints of the *tænia lata* are shorter and broader, and adhere together in a different manner; and that the pores leading to the oviducts are situated not on the edge of each joint, but in the centre of its flat surface. This variety is not so easily broken across as the former; and therefore its segments are less liable to be voided in a separate form. It is probably shorter also than the *tænia solium*. Fifteen feet has been supposed its average length. Marvellous stories, however, are told on this head. Boerhaave declares that he effected the expulsion of one, which was 300 ells long, from the bowels of a Russian.

The geographical distribution of these two species of *tænia* forms a curious part of their history, and throws some light upon the doubtful question of their origin. In England, Holland, and Germany, the *tænia solium* is common, and the *tænia lata* very rare. In Russia, Poland, and Switzerland, it is just the reverse: the *tænia lata* prevails; the *tænia solium* is seldom seen: while in France one species is nearly as frequent as the other.

---

#### ON THE VITAL PROCESSES AND THE IN- FLUENCE OF THE ATMOSPHERE UPON ANIMALS.

BY PROFESSOR LIEBIG.

[Translated from the "Annalen der Chemie und Pharmacie."]

---

THE absorption of food and oxygen are the primary conditions necessary for the support of life. In each moment of time during life we take in oxygen by the organs of respiration. No intermission is to be observed so long as the animal lives. The discoveries of physiology show that the body of a man who is grown up with sufficient nourishment, after twenty-four hours neither increases nor diminishes in weight; yet the quantity of oxygen which is absorbed during this time is very considerable. According to Lavoisier's experiments, a grown man in one year absorbs from the atmosphere 746 lbs. of oxygen gas; according to Menzies 837 lbs.; and yet we find the weight of the body at the commencement and end of the year quite unaltered, or the increase or diminution varies only a few pounds. One may ask where is this immense

quantity of oxygen gone to which an individual in the course of one year absorbs. This question can be answered with perfect certainty. No part of the absorbed oxygen remains in the body, but it again goes out combined either with carbon or hydrogen. The carbon or hydrogen of certain components of the animal body combine with the oxygen absorbed by the skin and lungs, and they are separated in the form of carbonic acid and the vapour of water. With each respiration during each moment of life, certain parts of the animal body separate themselves from it, after they have entered whilst in the body itself into combination with the oxygen of the atmospheric air. If, in order to have some data for our calculations, we assume with Lavoisier and Seguin, that a grown up-man daily absorbs  $32\frac{1}{2}$  ounces of oxygen ( $46037$  cubic inches  $= 15661$  grammes), and we assume the mass of blood to be  $24$  lbs., containing  $80$  percent. water, then it follows from the known composition of the blood that, in order perfectly to change the carbon and hydrogen of it into carbonic acid and water,  $66040$  grammes of oxygen are required, which would be taken into the body of a grown man in four days and five hours. It matters not whether the oxygen goes to the components of the blood, or to other matters which are rich in carbon and hydrogen in the body. It cannot hinder the conclusion, that in the body of a man in four days and five hours so much carbon and hydrogen must be again added by way of nourishment as is sufficient to provide  $24$  lbs. of blood with these constituents. We first assume that the weight of the body does not change, that it shall keep its normal condition. This supply comes from the food. A grown man, in a state of moderate exercise, consumes daily  $18.9$  ounces of carbon. This follows from an accurate determination of the quantity of carbon, which by means of the food is absorbed into the body, and also by the separation of that quantity which is got rid of by the fæces and urine unburnt, or, if one may so express it, in some other form than in that of an oxygen compound. The numbers here stated are the average consumption of  $856$  billeted soldiers. These  $18.9$  ounces of carbon escape by the skin and lungs in the form of carbonic acid gas.  $37$  ounces of oxygen are required to change these

$18.9$  ounces of carbon into carbonic acid gas. According to the analytic results obtained by Boussingault (*Annales de Chim. et de Phys.*, lxx. s. l. p. 136), a horse consumes in  $24$  hours  $79\frac{1}{2}$  ounces of carbon. A cow which is giving milk,  $70\frac{1}{2}$  ounces. The quantities of carbon here mentioned are separated as carbonic acid. The horse has used in  $24$  hours  $13\frac{1}{2}$  lbs. of oxygen for the conversion of the carbon into carbonic acid, and the cow  $11\frac{1}{2}$  lbs.

It is clear that the quantity of nourishment which the animal body requires for its support is in exact relation to the oxygen absorbed, because no part of the oxygen which is absorbed goes out again from the body, excepting in the form of a carbon or hydrogen compound; and further, because, in a normal state of health, the carbon and hydrogen which go out are again replaced by carbon and hydrogen, which are supplied by the food. Two animals, which absorb unequal quantities of oxygen in equal times, by means of the skin and lungs, consume, in a similar ratio, an unequal weight of the same food. In equal times, the quantity of oxygen used may be expressed by the number of respirations. It is clear that the quantity of food to be eaten varies, in the same animal, according to the strength and number of the respirations. A child whose organs of respiration are in greater activity than those of one who is grown up, must take more frequently, and proportionably more nourishment. It can less easily endure hunger: a bird dies from want of food on the third day; a snake which, during an hour's breathing under a glass case, scarcely uses so much oxygen that the carbonic acid produced therefrom can be observed, can live three months or longer without food. In a state of rest, the number of respirations amounts to less than in a state of exercise and work. The quantity of nourishment necessary in these states must be in the same proportion: an excess of nourishment and a want of inspired oxygen (that is, of exertion), and also strong exercise (which necessitates a greater measure of nourishment) and feeble organs of digestion, are incompatible with each other. The quantity of oxygen which an animal inspires is not alone dependent on the number of the respirations, but also on the temperature of the inspired air.

The cavity of the chest of an animal has an invariable size; with each inspiration a certain quantity of air enters, which, as regards volume, may be looked upon as constant; but its weight, and the weight of the oxygen which is absorbed in it, does not remain constant. In the warmth the air expands, and in the cold it contracts: in an equal volume of air, which is colder or warmer, we have an unequal weight of oxygen. If a grown-up man inspires 46,037 cubic inches of oxygen, at a temperature of  $25^{\circ}$ , the weight of this amounts to  $32\frac{1}{2}$  ounces. If the same volume of oxygen is inspired at a temperature of  $0^{\circ}$ , 35 ounces are absorbed in the same time. In summer and winter, at the Poles and Equator, we inspire an equal volume of air: and if we, in summer, absorb  $31\frac{1}{2}$  ounces, then at a temperature of  $0^{\circ}$  (the number of respirations being the same), the quantity of absorbed oxygen amounts to 35 ounces. In Sicily, at a temperature of  $35^{\circ}$ , to  $28\frac{1}{2}$  ounces; at a temperature of  $10^{\circ}$ , to 36 ounces. The oxygen gas taken up goes out again both in summer and winter, altered in the same way. We expire more carbon at low temperatures than at higher ones, and we must consume more or less carbon in food in the same proportion; in Sweden, more than in Sicily; near Giessen, in winter, an entire eighth part more than in summer. Even when we consume an equal quantity of food (as regards weight) in cold and warm places, a never-failing wisdom has ordered that this food should differ, to the greatest extent, in the carbon it contains. The fruits which the southern eats, contain, when fresh, not more than 12 per cent. of carbon; whilst the fat and train oil of those near the poles contain from 66 to 80 per cent. It is not difficult to live moderately in hot countries, or to endure hunger at the equator; but cold and hunger produce a more rapid consumption of the body.

The changes taking place in the constituents of the food, by means of the oxygen distributed through the body by the circulation, are the source of animal heat: all living things, whose existence depends on an absorption of oxygen, possess a source of warmth independent of the surrounding atmosphere. This truth is established in all animals, and extends to the germinating seed, the bloom of plants, and

the ripening fruit. Warmth is only produced in those parts of animals to which arterial blood, and thereby the oxygen absorbed in respiration, can reach: hair, wool, feathers, possess no temperature which is peculiar to them. This increase in temperature of the animal body, or, if we so express it, production of warmth, is, throughout all things, and under all circumstances, a consequence of the combination of a combustible material with oxygen. In whatever form, also, the carbon may combine with the oxygen, the act of combination cannot proceed without being accompanied by the development of warmth; it makes no difference whether it ensues slowly or quickly, whether it proceeds at a high temperature or a low one; the quantity of warmth which is set free is always unaltered: the carbon of the food, which is changed into carbonic acid in the body, must produce just as much warmth as if it were burnt directly in oxygen or in the air; the only difference is, that the quantity of warmth produced is distributed in unequal times. In pure oxygen the combustion goes on quicker, and the temperature is higher; in the air the combustion is slower, the temperature is lower, but it continues longer. It is clear that the number of degrees of warmth which are set free must increase or diminish with the quantity of oxygen supplied by the process of respiration in equal times; animals which breathe strongly and quick, and therefore consume much oxygen, possess a higher temperature than others who, in an equal time and equal volume, absorb less for the warming of their bodies. A child has a temperature of  $39^{\circ}$  C.; a grown-up man,  $37.5^{\circ}$ ; a bird has a higher temperature ( $40^{\circ}$ - $41^{\circ}$  C.) than a four-footed beast ( $37^{\circ}$ - $38^{\circ}$ ), or a fish or amphibious animal, whose proper temperature is  $1\frac{1}{2}$  or  $2^{\circ}$  above their surrounding medium. All animals are warm-blooded; but only in those which breathe by lungs is the proper temperature entirely independent of the temperature of the surrounding medium. The most certain observations show that, in all climates, in the most temperate zones, as well as at the equator or at the poles, the temperature of man, and of other so-called warm-blooded animals, never changes; yet how different are the conditions of life in

which they live. The animal body is a heated body, which behaves to its surrounding medium like all heated bodies: it receives warmth when the external temperature is higher, it gives warmth when it is lower than its own proper temperature. We know that the rapidity of cooling in a warm body increases with the difference of its own proper temperature, and of the medium in which it is placed; that is, the colder the surrounding medium is, in so much the shorter time the warm body becomes cold. But how different is the loss of heat which a man suffers in Palermo, where the external temperature is near that of the body, and the loss of a man who lives at the Pole, where the temperature is  $40^{\circ}$ - $50^{\circ}$  lower. But experiment shows, notwithstanding this exceedingly unequal loss of warmth, that the blood of those at the north pole possesses no lower temperature than of those in the south of Europe, who live in so different a medium. These facts, taken in their true meaning, show that the heat lost is as quickly renewed in the animal body; in winter this renewal ensues quicker than in summer; at the poles quicker than at the equator. Now, in different climates, the quantity of oxygen which goes into the body by respiration varies with the temperature of the external air: the quantity of inspired oxygen increases with the loss of warmth, from cooling; the quantity of carbon or hydrogen necessary for combining with this oxygen must increase in a similar proportion. It is clear that the compensation of warmth is effected by means of the changes in the component principles of the food, which combine with the inspired oxygen. Employing a common-place, but not the less accurate comparison, the animal body, thus viewed, acts as a fire furnished with fuel: it matters not what forms the food gradually assumes in the body, what changes, also, it may undergo; the ultimate changes which it experiences are the change of its carbon into carbonic acid, and of its hydrogen into water: the nitrogen and unoxidized carbon are separated in the urine and the solid excrements. In order to have a proper temperature from the fire, we must put on quantities of fuel varying as the external temperature. As regards the animal body, the food is the fuel; by means of its oxydation, effected by proper admission of oxygen,

we obtain the warmth which is liberated. By exercise in cold air, during winter, the quantity of inspired oxygen is increased. The necessity for nourishment rich in carbon and hydrogen is also increased in the same proportion; and in satisfying this necessity, we obtain the most effectual protection against the severest cold. He who hungers is cold; and every one knows that the beast of prey of the northern climates far exceeds in voraciousness that of the southern.

In the cold and temperate zones, the air, which unceasingly endeavours to consume the body, forces us to work and exertion to procure the means of counteracting this inward consumption; whilst, in warm climates, the demands for the procuring of food are by no means so urgent. Our clothes are but equivalents for our food. The warmer we clothe ourselves, the more we lessen the necessity for eating; because the loss of warmth, the cooling, and therewith the compensation to be effected by food, is lessened. If we went naked, as the Indians, or were exposed to cold in the North by hunting or fishing, we should be able to devour half a calf, and afterwards more than a dozen tallow candles, as warm-clothed travellers with astonishment have told us. We should be able to consume the same quantity of spirit, or of oil, without injury; because the carbon and hydrogen which they contain serves to counterbalance the external temperature. The quantity of food necessary to be eaten, according to the foregoing principles, should be adapted to the number of respirations, the temperature of the inspired air, and to the quantity of heat which we give out. No isolated opposing facts can change the truth of this law of nature. The Neapolitan cannot consume more carbon and hydrogen in his food than he expires; and no inhabitant of the North can expire more carbon or hydrogen than he has consumed in his food, without inflicting a transitory or permanent injury on his health, except he be in a state of disease or of hunger; conditions we will somewhat nearer consider. The Englishman finds with regret his appetite, which gives him often-returning enjoyment, failing in Jamaica, and he succeeds, in fact, by means of Cayenne pepper and the strongest stimulants, in taking the same

quantity of food as in his native country; but the carbon of this food which goes into the body is not consumed. The temperature of the air is too high, and a relaxing heat allows of no increase of the number of respirations (by means of exercise and exertion) to proportion the consumption of the body to that which has been eaten. Those patients in England whose diseased organs of digestion lose wholly or partially the power of changing the food into that state in which it is best fitted to combine with oxygen, by way of counteraction are sent to southern countries, where the quantity of inspired oxygen is lessened in so great a degree, and an improvement in health is most evident. The unhealthy organs of digestion have power enough to proportion the small quantity of food they are able to take to the lessened quantity of oxygen which is absorbed. In colder climates the oxygen acts even on the lungs themselves. In summer, among us, in Germany, liver diseases (carbon diseases) are most prevalent. In winter, diseases of the lungs (oxygen diseases). The cooling down of the body, from whatever cause it occurs, necessitates a greater measure of food. Simply remaining in the open air, whether in a coach or on the deck of a ship, increases, by radiation and evaporation, the loss of warmth: even without any exercise we are constrained to eat more than usual. The same is true of persons who are accustomed to drink large quantities of cold water, which passes off again at a temperature of  $37^{\circ}\text{C}$ . It increases the appetite; and feeble constitutions must, by persevering exercise, take into the body oxygen sufficient to compensate for the warmth which is lost. Strong and continued speaking and singing, the crying of children, moist air, all these exercise a determinate recognizable influence on the quantity of food necessary to be eaten. In the preceding remarks, it has been assumed that it is especially the carbon and hydrogen which serve to combine with oxygen, and to produce the animal heat. The simplest observations shew, in fact, that the hydrogen of the food plays a no less important part than the carbon.

The whole process of respiration appears in most perfect clearness when we consider the state of a man or animal kept from all food. The mo-

tions of respiration remain unaltered. Then, as well as previously, oxygen is absorbed, and carbonic acid and vapour of water expired. We know, with indubitable certainty, whence the carbon and hydrogen originate; for with the continuation of the fast, we see the carbon and hydrogen of the body lessening. The first action of hunger is to cause an absorption of fat. This fat is neither to be recognized in the scanty fæces nor in the urine. Its carbon and hydrogen are passed off by the skin and lungs in the form of compounds of oxygen. It is evident that these components of it have served for the purposes of respiration. Each day  $32\frac{1}{2}$  ounces of oxygen enter the body, and these going out, remove a part of the body of him who starves. (Currie saw a patient who could not swallow, lose 100 pounds in weight in a month; and a fat pig, which fell over a precipice, lived 160 days without food, and lost above 120 pounds in weight.—*Transactions of the Linnean Society*, vol. xi. p. 411). The state of the dormouse, and also the periodic accumulation in other beasts, of fat, which, at other periods of their lives, disappear without leaving a trace, all these well-known facts make it certain that the oxygen, in the process of respiration, makes no selection among the substances which are fitted to combine with it. The oxygen combines with all that is presented to it; and want of hydrogen is the only reason why it generally forms carbonic acid: for, at the temperature of the body, the attraction of hydrogen for oxygen far exceeds that of carbon for oxygen. In fact, we know that a graminivorous animal expires a volume of carbonic acid equal to that of the oxygen it inspires; while, by carnivorous animals, which are the only class which eat fat in their food, more oxygen is inhaled than answers to the volume of carbonic acid which is expired. It has been shewn by accurate experiments that, in many cases, carbonic acid is only expired equal to half the volume of oxygen. These observations are capable of no refutation. They are more convincing than all the artificial phenomena called forth at will, which we name experiments—experiments which are quite unnecessary, and destitute of all weight, if the opportunity for observation presents itself naturally, and this opportunity

is skilfully employed: in those starving not only the fat, but, by degrees, all the solid matters capable of solution, disappear. In the wasted body of one who starves, the muscles become thin and soft; the power of contraction is lost; all the portions of the body which possess a power of passing into a state of motion (by being redissolved) have served to protect the rest of the structures from the all-destroying action of the atmosphere. In the end, the component parts of the brain take part in the process of oxydation; then follows wandering, delirium, and death. That is, all opposition ceases. The chemical process of decay begins; all parts of the body combining with the oxygen of the air. The time in which one who starves dies, is determined by the state of fatness, by the state of motion (exertion and work), by the temperature of the air, and is, at last, dependent on the presence or absence of water. A certain quantity of water evaporates through the skin and lungs, by the escape of which, as the necessary condition for the communication of motion, death is accelerated. There are cases in which, by means of undiminished water-drinking, death did not take place for twenty days, and, in one case, not for sixty days. In all chronic diseases, death follows from the same cause, viz. the action of the atmosphere. If those matters are wanting which are appointed in the body for the support of the process of respiration; if the organs of the sick person refuse to perform their function; if the power is lost of changing for their own protection the food which is taken into that state in which its components can combine with the oxygen of the air, then are their own substances, the fat, the brain, the substance of the muscles and nerves, used for this purpose. The actual cause of death is, in these cases, the process of respiration—the influence of the atmosphere. Want of nourishment, and want of power to convert it into the component parts of the body, is want of an opposing force. This is the negative cause of the cessation of the vital activity. The flame goes out because the oil is consumed. It is the oxygen of the air which has consumed it. In many states of disease, substances are produced which cannot be used for the purposes of assimilation. They are removed from

the body simply by abstaining from food. They disappear without leaving a trace, because their component parts enter into combination with the oxygen of the air. From the moment in which the function of the skin and lungs undergoes interruption, substances rich in carbon appear in the urine, which changes its ordinary colour into brown. The process of respiration is the falling weight—the stretched spring which keeps the clockwork in motion. The act of respiration is the stroke of the pendulum which regulates it. We know in our ordinary clocks, with mathematical certainty, the changes which, by lengthening the pendulum, or by external temperature, will be produced on its ordinary rate of going; but only by a few is the influence which the air and temperature exercise on the body of man clearly recognized, though the detecting of the conditions necessary to keep him in the normal state is not more difficult than it is in an ordinary clock.

[To be continued.]

---

#### ON THE REMEDIAL EFFICACY OF SELTZER WATER.

By EDWIN LEE, M.R.C.S. &c.

(For the *London Medical Gazette*.)

---

SELTZER water is regarded by most persons in England but as an agreeable cooling beverage. It possesses, however, great medicinal virtues, and is extensively employed in the practice of medicine upon the continent, and from having myself frequently had occasion to witness its beneficial effects, I am desirous of recalling the attention of the profession to it. It is one of the very few mineral waters applicable in acute disease; and its use in febrile affections is generally found to be highly advantageous, from its properties in cooling the system, allaying thirst, augmenting the urinary and cutaneous secretions, and cleaning the tongue and fauces from the viscid mucus which so frequently accumulates upon them; the proportion and admixture of its constituent parts (16 grains mur. soda, 15 grains carb. soda, 15 cubic inches carbonic acid gas, to the pint of water), rendering it admirably adapted for these purposes. Dr. Wetter, of Berlin, speaks

very highly of its efficacy when given in small and frequently repeated doses in the fevers which prevail in summer with a degree of erythism of the upper part of the alimentary canal (gastric fevers), but unattended by acute inflammation, especially when there is repeated vomiting, which so frequently resists the measures employed against it. Dr. Cullen was likewise in the habit of employing this remedy, mixed with whey, in several diseases attended with fever. Of course the previous removal of effete matters from the alimentary canal by laxatives is to be attended to. In irritation of the urinary organs, attended with gravel, or with a secretion of ropy mucus from the bladder, its effects are strongly marked, as also in stomach and hepatic derangement, with the character of torpor, or of irritability, with acidity and pyrosis, as is frequently found to occur in those who have been accustomed to the abuse of spirituous liquors. Its habitual use is no less advisable in cases of enlarged mesenteric glands, and the attendant impaired digestive power occurring in scrofulous children, in which case the addition of a portion of milk might often be made with advantage. It is, however, in some chronic affections of the air-passages, and in the early stage of phthisis, that this water possesses the greatest efficacy, and in which it is more frequently employed than in any other class of complaints. Hufeland said of it, with reference to its effects in phthisis—"In this disease, when other powerful remedies produce no good effects, Seltzer water has often an extraordinary efficiency. When there exists relaxation of the mucous membrane, by the exciting property peculiar to it, the energy of the relaxed vessels and mucous glands becomes re-established. In the tubercular kind, it resolves obstructions, without exciting inflammatory irritation; and where inflammatory complication exists, it regulates the abnormal secretion, and often prevents suppuration. I say all this from great experience, and could adduce many cases of success. Seltzer water seems to contain the due admixture of principles required in this disease; viz. a slightly stimulating action, and the faculty of producing an increase in the power of the lungs and glands without causing determination of blood to them, or

accelerating the circulation through the body; and produces the best effects in this disease when mixed with a third part of warm milk, especially ass's milk\*. In this, as in all chronic diseases, a large quantity, as a bottle, or a bottle and a half a day, or sometimes more, is requisite; and as it is now freely imported, there is no obstacle to procure it in any quantity that may be desired: for, with regard to the artificial Seltzer water, as it has been hitherto manufactured, it is not so well adapted for remedial purposes as are the imitations of other waters, on account of its being too much charged with gas; though this might easily be altered, and I trust will be in the future manufacture of Seltzer water at the establishment in this town. In a little brochure published last year†, to which I may refer those desirous of more detailed information respecting the composition and effects of Seltzer water, the question is considered, "Can the artificial be an efficient substitute for the natural Seltzer water?" and the opinions of M. Caventou on the subject are quoted. This gentleman says, "the fictitious Seltzer water produces, in a great number of patients, accidents which necessitate the substitution of the natural water for it. The sudden disengagement of carbonic acid gas causes, in many persons, a no less sudden distension of the stomach, accompanied with troublesome, and even painful eructations, agitation, and a greater or less degree of congestion towards the brain. We have seen in some cases, where there was great sensibility of the stomach, and even where this organ was influenced, that the artificial Seltzer water could not be borne; whilst the natural water was salutary. On other occasions, where Seltzer water has been administered to allay vomiting, we have seen the too sudden and too copious separation of the gas in the artificial water increase this symptom; whereas the natural water removed it. Lastly, it is generally remarked that the natural Seltzer water is infinitely better adapted to pulmonary cases than the artificial. The same observation applies to chronic hepatitis."

\* *Practische Uebersicht der vorzüglichsten Heilquellen Deutschlands.*

† *Memoire sur l'Eau de Seltz Naturelle, ses vertus curatives et hygieniques.* Bailliere, Regent Street.

The author of the above mentioned pamphlet speaks highly of Seltzer water as a wash for the mouth, and of its beneficial effects upon the teeth and gums, both as regards their appearance, and also in arresting the progress of caries.

Brighton, 170, North Street,  
April 15, 1842.

### CASE OF DIABETES MELLITUS.

*To the Editor of the Medical Gazette.*

SIR,

IF you deem the following case worthy of being placed on record, its insertion in the *MEDICAL GAZETTE* will oblige, sir,

Your obedient servant,  
JOSEPH BELL.

Barrhead, April 5, 1842.

March 24th, 1841.—John H., æt. 50 years, a native of the North of Scotland, of ordinary stature, by trade a sawyer. He is of a relaxed leucophlegmatic appearance. About angles of lower maxillary bone there are several vestiges of suppurated glands, some of which are still enlarged and painful. He states that for nearly a year he has been passing a large quantity of urine, and that it has greatly increased within the last four months. During the last twenty-four hours he has voided 108 fluid ounces of a light straw-coloured urine; it has a smell like honey, and of sweet taste. He feels very feeble, but his appetite is not impaired: thirst considerable; tongue covered with a dirty white or buff-coloured fur. He is occasionally troubled with pain shooting through head, and giddiness is sometimes troublesome.

He has had palpitation of heart for many years; pulse 78, full; the palpitation of radial and ulnar arteries, as well as their phalangeal branches, is distinctly visible through integuments. Bowels said to be regular. The specific gravity of urine was found to be 1.0493. It yielded a large quantity of saccharine matter. No traces of urea could be detected.

Habt.  $\mathcal{R}$  Tr. Opii,  $\mathfrak{z}\text{ij}$ .; Tr. Ferri Muriat.  $\mathfrak{z}\text{ss}$ .; Aq. Puræ,  $\mathfrak{z}\text{xij}$ . M. sumt.  $\mathfrak{z}\text{j}$ . t. d. et habt.  $\mathcal{R}$  Sulph. Quin. gr. xxxvi.; Conser. Rosæ,  $\mathfrak{z}\text{iiss}$ . M. ft. mass. et divid. in pil. xxiv. Capt. unam 6ta. q.q.h.

To have for diet stale bread, mutton-chop, roast beef, biscuit, &c.

29th.—Since he commenced taking his medicine urine has gradually decreased; during the last twenty-four hours he has voided 56 fluid ounces, and says he made a similar quantity yesterday. Specific gravity is now 1.035, and less saccharine matter contained. General health improving; pulse 68; no pain of head; palpitation less; thirst less; tongue cleaner.

Pergat.

April 10th.—The quantity of urine voided daily since 3d inst. amounts to 42 fluid ounces. Specific gravity 1.026. Saccharine odour and matter gone; tongue clean; general health continues to improve; pulse 66; bowels regular.

REMARKS.—Having frequently witnessed the good effects of opium and tr. ferri muriat. in cases of diabetes, I was induced in the foregoing instance to prescribe these two preparations, along with the sulph. quinin. in the same manner (or nearly so) as recommended by C. Clay, Esq., of Manchester, in the *Lancet*, Oct. 10th, 1840. The happy change which followed the use of the medicine in this case was most satisfactory, and has been as yet permanent; the man up to this moment having no return of the complaint.

The following I think is the formula recommended by Mr. Clay:—

$\mathcal{R}$  Tinct. Opii,  $\mathfrak{z}\text{iiss}$ .; Tr. Ferri Muriat.  $\mathfrak{z}\text{ij}$ .; Sulph. Quin. gr. viij.; Aq. Destill.  $\mathfrak{z}\text{vj}$ . An ounce to be taken three times a day.

I would prefer giving the sulph. quin. separately, in form of pill, as being more elegant, and more easily taken by the patient. The remedy can be merely recommended on empirical grounds, however unsatisfactory this may appear to those who would wish to see the disease treated on philosophical principles—a circumstance much to be desired; but really when the true pathology of diabetes is so far from being elucidated (despite of the laborious investigations of many eminent physicians), we are glad to avail ourselves of any remedial agent which has been found, even in a few cases, to procure relief.

## ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

*De la Menstruation considérée dans ses rapports Physiologiques et Pathologiques.* Par A. BRIERRE de BOISMONT, D.M. &c. &c. Ouvrage couronné par l'Académie Royale de Médecine. Baillière, Paris, 1842. 8vo. pp. 560.

*On Menstruation, physiologically and pathologically considered.* By A. BRIERRE de BOISMONT, D.M. &c. &c. Prize Essay of the Royal Academy of Medicine.

ALTHOUGH we cannot venture to say that M. de Boismont holds out the attraction which all so eagerly seek for, namely, novelty of facts or opinions, yet it is due to him, and proper for the information of our readers, that we should state the conviction upon our minds after an attentive perusal of his work. In the first part of the work—devoted to the physiology of the subject—he gives us many very interesting statistical tables, which establish, in a much more satisfactory and convincing manner than has been done by any preceding writer, various facts relating to the physiology of the very important function of menstruation. We shall reserve to ourselves the privilege of passing over much elementary matter which has very fairly its place in a professed treatise upon the subject, but which is unsuited to our condensing pages and purpose. As a proof that M. de Boismont enters at once "in medias res," we quote his first sentence, "L'époque de la puberté est enfin arrivée." The well-known changes that occur at this period are briefly described, and an interesting statistical account is given of the age at which menstruation first occurs in the country, towns, and the metropolis, in females of the lowest, the middling, and the highest classes of society. Twelve hundred females, selected from these different grades, form the basis of his inquiries, which were commenced ten years ago. The conclusions are in keeping with the generally received opinions upon the subject. In the country the menstrual function was, upon the average, found to occur for the first time several months later than

753.—xxx.

in cities; nearly fifteen being the average age. Very few, too, of these women of the lower classes menstruated before eleven years of age; while, among the higher classes, a certain number menstruated as early as seven, eight, nine, or ten years. In towns sufficiently distant from the metropolis to be beyond its sphere of attraction, of 205 women the greatest number began to menstruate at fourteen years of age. In proportion, in fact, as an approach was made to the capital, the age at which this function was first established was found to decrease. As may be imagined, exceptions to this general rule are not uncommon. In the metropolis itself, of 359 females the greater number began to menstruate at fourteen years of age; but in a much larger proportion than in the country and towns, the period varied from nine to thirteen years. The train of inquiry pursued by the author to arrive at this conclusion is ingenious; and it shews how much care and accuracy are required in statistical investigations: for, in this instance, without these important requisites, an exactly opposite result to the true one would have been deduced. The remarks M. de Boismont offers upon the injurious influence of modern habits and education, in forcing premature menstruation in young females, especially among the higher classes, and those who "ape their habits," are well and forcibly put, and cannot be perused without interest by the philanthropist as well as the medical practitioner. We have not the smallest doubt of the fact, which M. de B.'s observation has verified, that a strictly moral and religious education would have the effect of retarding the first appearance of menstruation in young females. The influence of climate upon the function of menstruation has rarely been contested. A few remarks upon this part of the subject are made by our author. It is well known that girls of nine or ten years' of age who menstruated regularly in the East Indies, have ceased to do so, upon their arrival in this country, for four or five years\*. Various cases are scattered through medical writings of children of two or three years of age who menstruated regularly. In most of these instances the sanguineous discharge

\* Cyclopædia of Practical Medicine, vol. iii. p. 110.

was, no doubt, accidental hæmorrhage rather than true menstruation. In a few cases, however, menstruation has been quite normally established at an unusually tender age, and was accompanied by all the other signs of puberty. M. de Boismont adds three striking examples to the number. We, too, have known such cases; but still, with Moreau and others, we are quite convinced that such precocious discharges usually constitute a state of disease which requires relief. Experience, too, has established the fact, which might have been anticipated, that, when the menstrual function is so very early in its appearance, weakness and premature old age are the ordinary results. Among other influences which act upon the establishment of puberty in females, and which it is very difficult to appreciate correctly, is that of peculiarity of temperament. M. de B. touches upon this subject but briefly. His statistical records, however, prove that females of a sanguine temperament menstruate earlier than those of a "lymphatic" temperament.

*Appearance of the Menses with or without symptoms.*—The author comes to the, no doubt correct, conclusion that menstruation is established, in most women, without the agency of medical means, and by the unassisted efforts of nature; and that not unfrequently the health has been injured, and the menstrual functions retarded, by attempts to establish it by medical means, which were apparently judicious. The knowledge of these facts, and important ones they are although they are too frequently lost sight of, ought to guide the conduct of the physician. When there is no trace of organic mischief, and the other functions are regularly performed, he should restrict himself to the general means of preserving health. The period that elapses between the first symptoms that are premonitory, and the actual appearance, of the menstrual flux, is liable to great variations. In some females the premonitory symptoms lasted but a day; in others as long as four years, or more. But, however long may be this period, some other necessity than the assumed one of the non-appearance of the menses must exist to justify the practitioner in attempts to hasten the just appearance of the discharge. Although the whole of the female economy

is more or less influenced by the first approach of menstruation, the genital organs and the nervous system are more decidedly so. Without precisely admitting the utility of the mathematic precision with which M. de B. has attempted to trace the progressive changes that take place in the size of the uterus and vagina from early infancy to the age of puberty, which, of course, vary greatly in different individuals, the pages devoted to this inquiry contain many observations that are worthy attention, inasmuch as they show the exquisite skill with which nature gradually prepares important organs for very important duties. M. de B. thinks it probable—we confess we do not—that the changes in the diameters of the uterus, which occur previous to puberty, explain those pains of which the uterus is so frequently the seat at the approach of menstruation, and which vary in severity from a slight and transient inconvenience, to great and long-continued suffering. The constantly varying and almost as constantly perplexing "nervous symptoms" which occur so frequently at the approach of puberty in young females, especially among those of the higher ranks of society, are too well known to be formally dwelt upon. Many of the author's remarks, however, upon this part of the subject, are practically of much importance. Among other organs that commonly suffer amidst the general disturbance of the period referred to, the head is often the first affected. In many cases, the headache that is complained of depends upon plethora, but it should be borne in mind by the practitioner that this symptom more commonly depends upon derangement of the nervous system. We frequently have to contend with headache of the severest kind in young females in whom there are none of the signs of plethora. "It would be in vain that we persisted in combating this symptom, in a crowd of cases, by antiphlogistic means: it would resist repeated bleedings." It would be scarcely possible to enumerate the different forms and types of these headaches. Sometimes the whole of the head is affected; sometimes only one side, constituting the "migraine," or hemicrania: the back, the forehead, or the sides of the head, may suffer. The pain may be intense, or dull. Sometimes it is continued, more fre-

quently it has remissions. "In one case it presented the form of a tertian intermittent." Like the pains in the loins, the headache ceases on the appearance of the menses, but it frequently returns, like the former, with each menstrual period.

To many of our readers it may seem an unnecessary waste of words to insist upon the folly and mischief of attempting to cure these headaches by repeated abstractions of blood. Yet in ordinary practice, how commonly is this error committed, in spite of the doctrines of teachers and numerous writers. And we would observe, that even when the nature of the case clearly contra-indicates the use of the lancet at all, and points to a very opposite mode of treatment, that a moderate bleeding very often produces a temporary relief, and that hence the inference is most erroneously drawn by the young and inexperienced practitioner, that if one small bleeding has done a little good, complete relief will follow a more determined employment of the same means. We, who have spent many years in trying to correct our own blunders, and in observing the blunders of others, have too often seen, as others must have also, the melancholy effect of bleeding for almost every pain, in almost every constitution and condition.

Various other symptoms indicative of the first approach of menstruation are mentioned by the author. We strongly suspect, although he does not mention the fact, that insanity, which he considers as a not unfrequent occurrence at this period, must have been dependent upon some hereditary predisposition, or upon some accidental cause, and that it neither can, nor ought to be, admitted into the catalogue of evils which sometimes appear owing to the effort of nature in establishing the menstrual flux. Among other symptoms which are referrible to derangement of the vascular system at the approach of puberty, M. de B. mentions a very unmanageable form of ophthalmia, which resisted every treatment, and which disappeared "as if by enchantment," when the catamenia appeared. At about the age of puberty it is not uncommon for a train of symptoms to occur which may easily be mistaken for formidable pulmonary disease." The breathing is often

short and difficult; the chest appears to be expanded with difficulty; the patient is breathless upon the slightest exertion. She frequently suffers from a nervous and spasmodic cough. We are frequently consulted for young females with a little dry, teasing, and almost constant cough, which is sometimes accompanied by spitting of blood; and the greatest anxiety is felt by the parents. An attentive exploration of the chest by a skilful stethoscopist will usually dissipate alarm. If the respiration is heard clearly during inspiration and expiration; if it be vesicular; if there are no "rales," and no abnormal sounds; and if, upon percussion, perfect resonance is heard, we may be satisfied the lungs are safe." (p. 62.) These, we would add, are the very cases in which the public are so constantly imposed upon by dishonourable and cruel knaves, by quacks, who care not what domestic misery they cause, if they can put money in their purse. True, they promise a cure, but "consumption" cannot be even mentioned without anguish to a mother.

*Quantity of the menstrual discharge.*—No wonder, considering the difficulty of forming a correct estimate upon this point, that different conclusions have been arrived at. Different observers who have devoted their attention to this part of the subject are greatly at variance. Some fix three ounces (English) as the average quantity: some, Sauvages and Freind, for example, sixteen or twenty ounces. For our own part we are quite satisfied that, even in the same woman, the quantity of the discharge varies on different days of its flow; that it varies greatly at different monthly periods, and that it is liable to be either diminished or increased by so many accidental circumstances, without any derangement of health, that the attempt is vain to fix a correct and average estimate of the quantity.

The next point considered by the author claims the attention of the practitioner, in order that he may secure the confidence of the public by giving correct opinions in reference to it. Of 654 women, 412 menstruated regularly after the first appearance of the discharge; 242 were "irregular" from the commencement. In 178 of these menstruation became regular after some time: in 65 it remained permanently

irregular. Two cases are related in which eleven and ten years elapsed before menstruation was regularly established; but with these exceptions the longest period before the function was regularly performed did not exceed six years from its commencement. The most frequent periods appear from tables given to be six months, and one and two years. The following are interesting results from the observation of 67 females. In three, "les regles" occurred every day for a year, and sometimes amounted to true hæmorrhage; and still these women remained healthy, and never felt weak. In 11, every eight and fifteen days. In one instance this irregularity persisted for several years every eight days; the health of the girl still remaining good. In 17 cases the discharge appeared every ten, fifteen, or twenty-one days, with occasional intervals of two, three, and four months.

In one instance the flux was very copious one month, less the next, and absent the third. This irregularity continued for a year. In nine the menses appeared every two or three months. In three of these at these periods for two years. In two for four years. In seven the periods were five, six, or seven weeks. Other variations are mentioned, which, after these examples, need not be detailed. There are many, and by no means unimportant practical hints to be drawn from these facts; one of which is the necessity of speaking doubtfully as to the regular establishment of menstruation, even when it has once appeared; another, that we are not confidently to predict mischief because menstruation is very irregular; a third, that nature *alone* not unfrequently establishes the normal discharge of the menses after it has been long irregular. Forty-two examples are given, showing that the period during which menstruation ceases altogether, after having once occurred, varies from a month to five-years. In ten instances the function was not regularly established until pregnancy and labour had been gone through. The case related by Bouvier is a rare one. The patient, of a delicate constitution, began to menstruate at the age of twenty-four. At this time she became deformed, and her health suffered. She continued capable, however, of performing her habitual duties until a

very advanced age; and at seventy years of age she was admitted into the hospital of Rochefoucauld; and during the two years that she remained in it, she menstruated regularly. She died at the age of seventy-two, and upon dissection the organs of generation were found to be in a healthy state.

In the fifth chapter we have a detailed account of the local and general symptoms which generally accompany menstruation, and of which the author thinks we ought to admit two distinct classes; in one of which the uterus is affected; in the other, the numerous organs that sympathise with the uterus. Of 360 women, 278 suffered from pain, generally of the uterus, but frequently of the intestines; these pains were sometimes slight and intermittent; at others intense and continued. Some of these women suffered only during their virgin state; in others the pains began after marriage. In many each attack of pain was diminished upon the expulsion of coagula. In 40 of the cases referred to, weight in the region of the uterus was complained of at the period of the menses, which was no doubt correctly attributed to a congested state of the womb and its appendages. This local congestion ceases with the cause that produces it, and thus we can distinguish it from disease of the uterus. Its frequent repetition may become the "point de départ" of those organic lesions to which the uterus is so liable. M. de Boismont "has frequently met with cases of uterine hæmorrhage in women who were otherwise healthy. In some it was considerable, and lasted several days, without any diminution of the general strength, or any marked expression of suffering in the general appearance. This intermitting hæmorrhage may last much longer in women who menstruate irregularly, even for years, and yet not compromise health." It is well we should know the little hazard that may attend such cases, but a prudent practitioner would be upon the alert during the continuance of such a state.

In 76 cases M. de Boismont observed tumefaction of the belly at the menstrual period: it existed generally at each period: sometimes only occasionally; sometimes the belly was hard and extremely tense. This abdominal swelling, depending no doubt upon flatus in the intestines, was sometimes

unaccompanied by pain; but it was frequently associated with such increased sensibility of the abdomen that the slightest pressure could not be borne.

We find nothing in the general sketch that is given of the various nervous and hysterical symptoms that are so often associated with the menstrual function, to arrest our attention. "In three cases the sense of vision was lost or greatly weakened during several periods," each return of menstruation being indicated by complete blindness, or by great weakness of sight. Sometimes, too, there was a perversion of taste and smell. As our readers are doubtless aware, much ingenuity has been excited, and numerous arguments indulged in, to account for the periodical flow of the menses. We are of opinion that this part of the subject might be fairly dismissed by the confession, that the cause of the periodical phenomena of either health or disease is beyond our reach. M. de Boismont has rather unnecessarily, we think, given some formal tables for the purpose of establishing the conclusion that the moon has no influence upon the menstrual function.

The chapter upon the duration of each menstrual period is interesting. Of 562 women, the discharge continued for eight days in the largest number: in only a rather smaller proportion for three days. Particular localities, temperaments, and modes of living, have much influence in causing these variations. Some women are "unwell" only for a few hours, others for a much shorter period, and still without any disturbance of health. Equal variations, too, as to duration, occur in the same women at different periods, and without any appreciable cause. Marriage very frequently renders women regular who before were not so. Upon the warmly disputed point of menstruation during pregnancy, the author says, "in five out of eight cases, the menses appeared for the first two, three, or four months after conception; in three, menstruation continued throughout the whole period of pregnancy." We have before, upon different occasions, touched upon this question, and we now briefly state that our personal experience convinces us of the fact, that menstruation may occur during several months or even during the whole of pregnancy; or, at least, to use the lan-

guage of Gooch, "that such a periodical discharge may occur that neither the patient nor the practitioner can distinguish from menstruation." The source of the menstrual discharge has also been much discussed. At present, all physiologists agree that the uterus produces it when the function is regularly performed; but it may, under extraordinary circumstances, be furnished vicariously by other parts. In the absence, too, of demonstrative evidence, it may be assumed that the menstrual flux exhales from the capillary vessels of the uterus, the vessels from which it flows belonging especially to neither the arteries nor veins.\*

Upon the subject of the final cessation of menstruation M. de Boismont adds nothing to what is generally known. His observations lead him to the conclusion, which we have no doubt is perfectly correct, directly as it is opposed to the popular belief, "that the critical age does not increase the mortality of women" (p. 245.)

The second part of the work on the Pathology of Menstruation contains a brief sketch of the various diseases which are, more or less, connected with derangement of the function.

## THE COLD WATER SYSTEM.

MORE than two years have elapsed since we gave an account of the new method of treating diseases in Germany by the external and internal use of cold water†. Since that period much has been written on the subject in Germany and France, and two English accounts of the plan are now lying before us. The first is written by our correspondent Mr. Edwin Lee, in the form of an appendix to the second part of his

\* Burdach, *Physiology*, by Jourdan, i. 296.

† MEDICAL GAZETTE, Oct. 12th, 1839.

treatise on the German Baths. The other is a substantive work by Mr. Claridge\*, the author of a Guide along the Danube.

The establishment visited by Mr. Lee is situated at Marienberg, on an eminence overlooking the town of Boppard, on the Rhine; Mr. Claridge resided at the original establishment at Gräfenberg, in Austrian Silesia.

Mr. Lee's account, though highly favourable, is tempered by sound professional criticism; while the unthinking enthusiasm of Mr. Claridge, a mere layman, makes one shrink from his statements; and as they are exaggerated on their very face, one hardly knows how much ought to be struck off to reduce them to plain truth. One's natural tendency in such a case is to disbelieve even facts which have got into bad company; and when we are told that the cure of acute disease in the hands of Vincent Priessnitz is mere child's play, we are tempted to ask whether the plan is not child's play altogether. When a tradesman asks us ridiculously much, says Lord Chesterfield, we offer him ridiculously little.

Yet, as the faithful chroniclers of every thing conspicuous which appears above the medical horizon, whether a steady light, or an *ignis fatuus*, we think it right to place our readers on a level with the knowledge of the age concerning the cold water cure, or, as it is often called, *hydropathy*.

How long has this system been at work under the guidance of Vincent Priessnitz? Neither Mr. Lee nor Mr. Claridge enables us to answer this question. According to the former, the house at Gräfenberg was built in 1824, and was soon insufficient to receive the numerous invalids; the latter begins his account with the year 1829,

when the patients amounted to forty-five only. Mr. Lee informs us that in 1830, the patients were five hundred and fifty-five in number; while Mr. Claridge's reckoning for the same year is only fifty-four. This discrepancy, however, is of small importance, as they both agree that the system has spread of late years. Mr. Lee says that "this method of treating diseases has been of late years very much in vogue in several parts of Germany;" and the lay advocate gives a list of forty-six establishments where it is carried into effect. They are chiefly in Germany, but a few are in France, Belgium, Poland, Russia, and Hungary.

Gräfenberg is an appendage of the small town of Freywalden (according to Mr. Claridge, Freiwaldau or Fréiwaldau). It is 70 English miles from Breslau, 200 from Dresden, and 260 from Berlin.

What is done at Gräfenberg? As it is easiest to ascend from particulars to generals, perhaps the most ready answer to this question will be to tell what was done with Mr. Claridge, who was suffering from rheumatism.

"The first thing he did was to request me to strip, and go into the large cold-bath, where I remained two or three minutes. On coming out he gave me instructions, which I pursued as follows:—At four o'clock in the morning my servant folded me in a large blanket, over which he placed as many things as I could conveniently bear, so that no external air could penetrate. After perspiration commenced, it was allowed to continue for an hour; he then brought a pair of straw shoes, wound the blanket close about my body, and in this state of perspiration I descended into a large cold-bath, in which I remained three minutes; then dressed and walked until breakfast, which was composed of milk, bread, butter, and strawberries (the wild strawberry in this country grows in abundance from the latter end of May until late in October); at ten o'clock I proceeded to the douche, under which I remained four minutes, returned home, and took a sitz and foot-bath, each for

\* Hydropathy; or the Cold Water Cure, as practised by Vincent Priessnitz at Gräfenberg, Silesia, Austria. By R. T. Claridge, Esq., &c. London. 1842.

fifteen minutes; dined at one o'clock; at four proceeded again to the douche; at seven repeated the sitz and foot-baths; retired to bed at half-past nine, previously having my feet and legs bound up in cold wet bandages. I continued this treatment for three months, and during that time walked about 1000 miles. Whilst thus subjected to the treatment, I enjoyed more robust health than I had ever done before; the only visible effect that I experienced was an eruption on both my legs, but which, on account of the bandages, produced no pain. It is to these bandages, the perspirations, and the baths, that I am indebted for the total departure of my rheumatism."

This sweating plan has a chapter dedicated to it with the exquisite title of "Hydrosudotherapia, or Sweating and the Bath." The patient is wrapped up in a blanket, feather-bed, counterpane, and sheet, till he resembles a mummy; perspiration comes on after a period varying from half an hour to two hours, and is then allowed to continue for a time also varying, according to the prescription of Priessnitz, from half an hour to two hours. Some patients are made to perspire daily, others every second or third day. The patient then proceeds to the cold-bath, in which he remains from two to eight minutes.

This, however, is by no means the universal treatment:—"Sweating is not administered to one-half of the patients who resort to Gräfenberg," says Mr. Claridge. Several other methods are used. Many patients are treated by the application of cold wet bandages; clysters of cold water are used for the cure of constipation as well as diarrhoea; not to mention injections into the ears, nostrils, and genitals. As for drinking cold water, this is the panacea for all human infirmities. It is right to drink it at all times of the day; yet, as Bacon says of goodness, that it admits no excess, but error; so water-drinking admits no error, but excess; for although it may be pursued

after breakfast, this must not be done so as to overcharge the stomach. The usual quantity drunk daily is from twelve to twenty glasses of water.

The baths themselves are of various sizes, such as whole baths, half baths, leg baths, finger baths, and what Mr. Claridge calls sitz baths, i. e. sitting baths, or bidets.

Nor are these the only methods by which impurities are eliminated from the blood:

" Aliis sub gurgite vasto  
Infectum eluitur scelus."

Some are taken into the forest, where the mountain streams are conveyed into pipes, and dashed upon their diseased limbs in the form of a douche, with a fall of ten, fifteen, or even twenty feet.

When Anacharsis was asked how the Scythians were able to go naked in winter, he inquired in reply, "How can you Greeks bear to leave your faces exposed?" "Because our faces are used to it." "And we Scythians are all face." Mr. Claridge, without quoting Anacharsis, adopts the same theory, and imagines that use might entirely supply the place of wool. For our own parts, we verily believe this to be mere moonshine, and that in spite of the *joli mot* of Anacharsis, both theory and practice are on the side of furs and flannel. The heat generated by a well-clothed body may easily supply the expenditure of a bare face; but if the thermometer is standing at 20° Fahrenheit, how is a simple body, without wool or sables, to supply the heat continually abstracted by the frozen atmosphere around? The Indians of North America, whom some regard as a race of Gymnosophists, dress most comfortably in winter, as any one may learn from Mr. Catlin; and we have no doubt that the ancient Scythians wore warm cloaks in cold

weather, in spite of Anacharsis and the anecdote-books.

How, too, can Mr. Claridge, who appeals to experience so stoutly in favour of Priessnitz and cold water, deny its evidence in favour of hot? Surely, if one single point is proved in the practice of physic, it is the benefit derived from the judicious use of hot springs. If some foolish people like to scald their mouths at Aix-la-Chapelle, or elsewhere, this does not prevent thousands from regaining their health at the same places; and, in truth, nearly in the same manner as at Gräfenberg, namely, by restoring the functions of the skin.

Mineral waters are avoided by all animals, says the lay witness. By no means, if we believe the stories of the manner in which the virtues of several springs have been discovered. But even if this were the case, and neither horse nor cow could be persuaded to drink of Harrowgate, or Wiesbaden water, are men, therefore, to be debarred from fountains of tried efficacy? Does any quadruped ever lie with its occiput in a pan of cold water, as a man does in Mr. Claridge's lithograph?

The diet at these cold water establishments is simple and salutary. The teatotaler here finds that he has by no means reached the simplicity of nature and Gräfenberg. Not only wine and other alcoholic liquors, but tea, coffee, and similar stimulants, are utterly unknown in these retreats. When Mr. Lee visited Marienberg the dinner consisted of soup, roast meat, potatoes and other vegetables, cutlets, and a plain pudding. Water was the only beverage. Breakfast consisted of bread and butter, with cold milk and water; and supper of the same articles, with the addition of stewed fruit.

The diet at Priessnitz's table appears, by Mr. Claridge's account, to be nearly the same. Even spices, such

as pepper and cinnamon, are prohibited: "Let us use," says Priessnitz, "seasonings which nature has given us, and leave to foreigners theirs!"

Lastly, we come to the practical question, what diseases are benefited by profuse perspiration, aided by pure air, early hours, and abstinence from stimulants? If we turn to Mr. Claridge, the list of water-cured diseases is so long, that it is like scanning the pages of Cullen's Nosology. One is inclined, like Goldsmith, to wonder at the obstinacy of people in dying, when a certain cure is so readily obtained; and in imitation of the old verse,

*Cur moriatur homo, cui salvia crescit in horto?*  
one inquires,

*Cur moriatur homo, cui Priessnitz suppetit undam?*

Mr. Lee supplies us with a better answer. Gouty and calculous disorders, some forms of chronic dyspepsia, fixed and shifting rheumatic pains arising from suppressed perspiration and exposure to cold, hysterical and spasmodic attacks, hypochondriasis, and long-standing intermittent complaints, whether in the form of ague, neuralgia, or irregular muscular movements, are benefited by this regimen. To these may be added leucorrhœa, disordered menstruation, piles, and syphilis, particularly when it has been of long duration, and much mercury has been taken.

We can easily suppose that in many or most of these diseases, a sudorific treatment may be of advantage; and especially when the syphilitic or mercurial poisons are circulating in the blood. There is evidence to show that salivation has recurred long after the termination of a mercurial course\*; so that it seems possible that mercury may circulate for some time, and then, by an effort of nature, be thrown out of

\* Christison on Poisons, p. 30-78.

the blood-vessels, and again produce its specific effect on the glands. Perhaps other poisons of a more subtle kind may, in a similar manner, be retained for some time in the system. As for the method pursued at Gräfenberg, enough has been said of it to excite rather than gratify our curiosity; but we have little doubt that, in spite of the extravagant praises of Mr. Claridge, "Hydropathy" contains something to reward the diligence of the eclectic physician.

#### MEDICAL SOCIETY OF LONDON.

A SPECIAL address was voted by the Medical Society to Dr. Clutterbuck on his retiring from the presidency, and a dinner given to him at the Albion Tavern. Mr. Pilcher, the new president, took the chair on this occasion, and the address was presented by Mr. Clifton, the secretary. It appears that Dr. Clutterbuck is one of the oldest members of the very respectable institution referred to.

#### ROYAL MEDICAL & CHIRURGICAL SOCIETY.

March 22, 1842.

##### THE PRESIDENT IN THE CHAIR.

*Notice of Cases of Plague contracted in the Lazaretto of Constantinople, in a Letter addressed to John Davy, M.D., F.R.S., Inspector-General of Military Hospitals, by Mons. PEZZONI, Conseiller d'Etat à S. M. l'Empereur de toutes les Russies, attaché à la Legation Imperiale près la S. Porte, in proof of the contagion of Plague; with Remarks by the former.—(Communicated by Dr. Hodgkin.)*

DR. DAVY observes, that the long-agitated and very important question, whether the plague is truly a contagious disease, or merely an endemic or epidemic, is not decided, appears clearly from two of the latest works published on this subject, viz., those of Clot Bey and Mons. Boulard. By the former an attempt is made to prove that the oriental plague is not contagious; whilst by the latter the contrary is maintained. This difference of opinion is the more remarkable, as their researches were conducted chiefly in the same country, Egypt, and about the same time, and in part in conjunction, both of them having belonged to a commission, which, for a considerable time, devoted

themselves to the investigation of the malady within the walls of a plague hospital. Dr. Davy remarks, that it is very desirable this question should be brought to an end; for, whilst it is undecided, there is little probability of any thing of moment being attempted in regard to the quarantine laws, which stand in so much need of being revised and reformed.

Dr. Davy states, that he left England in November last, employed by her Majesty's government on particular service, with instructions from the Foreign Secretary to make especial inquiries on the subject in question, in connection with the quarantine system. His mind, he says, was in a state of doubt on the point at issue, but if he had a bias, it was rather in favour of the non-contagiousness. At Constantinople he found all the medical men of any experience decided contagionists, but his own opinion remained the same till the month of June, when some facts came to his knowledge which appeared to be demonstrative that plague is really contagious. These facts were briefly the following:—At a time when Constantinople and its neighbourhood were free from plague, and had been so for three years, a vessel arrived from Egypt with cases of the disease on board, which, with the whole of the crew and passengers, their effects and merchandise, were disembarked, and placed in quarantine in the Lazaretto. Of the guardians and porters employed on this service, two contracted the disease, one of whom died. They belonged to a population of 800,000 souls, free from even the suspicion of plague, and had been so for three years, and which remained free up to the time of Dr. D.'s departure, the latter end of September, unless an exception be made in the case of a monk just liberated from the Lazaretto, and who, it cannot be doubted, contracted the disease whilst confined there. These two cases, with a notice of the monk and the son and daughter of the surveyor of the Lazaretto, are the subjects of the letter addressed by M. Pezzoni to Dr. Davy. The author is a gentleman long resident in Constantinople, a member of the Superior Council of Health, and who for many years has specially directed his attention to the question of the contagion of plague.

M. Pezzoni details very fully all the particulars connected with these cases; and there is appended to the letter a table of the patients admitted into the hospital of the Lazaretto from the 8th June to 15th August, as also a declaration on the part of M. le Dr. Robert, the director-general of quarantine, as to the existence of the disease. Our limits will not allow us to enter into these interesting details, but we may state that Dr. Davy expresses his desire that the facts brought forward by M. Pezzoni should have

the same weight with others as they have had with himself; and be held conclusive that plague *can* be propagated by contagion in persons in good health, and in a place and atmosphere in a healthy state. Dr. Davy adds, that about the same time that the proofs of the contagious nature of plague were afforded in the Lazaretto of Constantinople, a similar case occurred in the Lazaretto at Malta; the facts relative to which have been recorded by Dr. Gravagna, the principal health officer. Dr. Gravagna reasons much in the same manner as M. Pezoni against the non-contagionists, considering the occurrence of plague in a Maltese who communicated with plague patients in a ship from Alexandria (that city being then infected with plague), as proof demonstrative that the disease can be propagated by contact.

"If," adds Davy, "this be admitted to be proved, an important step surely has been made in the inquiry, which, followed up with caution, may ultimately bring the investigation to a satisfactory end, so that our knowledge of plague may be on a similar footing to that of variola, or any other disease which can be mentioned, that has been carefully and dispassionately studied."

Mr. Davis said, that having spent two years in countries infected with the plague, and passed two whole seasons in a plague hospital, he might be allowed to speak on the subject before the Society, and to express his most positive opinion that the plague is not a contagious disease. During the time he had mentioned he had spent whole days in company with those suffering under the disease; he had felt his patients' pulses, and continually attended on them every four hours; he had even for four or five successive nights slept close between two persons dying of the plague, yet he had never been affected by it. If the disease were contagious, how was it, he would ask, that there was a regular season for it—that it always commenced its ravages about December, continued till the middle of June, and then ceased? It was not true that plague was ever conveyed in ships or by merchandize. It always began in the interior; there it would often for many months, so long as the wind blew from the coast, continue its ravages without spreading; and then, with a change of wind, would make its way to the coast, and people would suppose it had been brought there by the ships. Numberless circumstances favoured its occurrence, altogether independently of contagion: fear, for instance. He remembered two young men while he was in Egypt, who came to him in great anxiety, because they had been appointed to medical service in the Plague Hospital, where they said if they once en-

tered they were certain they should die. He obtained other service for them; yet they both died of plague, though they had never been near the hospital. He would say a word of the treatment. At the time when he was in the habit of seeing the disease many different plans were employed. Some bled all their patients largely; but he believed that nearly all who lost much blood lost their lives also. Excluding such irrational modes of treatment as this, the deaths were, on the average, about one-half, whatever method was adopted; whether bark or tartar emetic, or opium or ether, or mercury, or any other. Near the end of his service a case occurred which he thought threw some light both on the nature of the disease and the right mode of treating it. At a great dinner given to their mess, he observed a servant, as he was handing some wine, stagger, and suddenly become exceedingly pale and dirty-complexioned. He had him at once removed, but he rapidly died of plague. It seemed to prove that one of the chief circumstances in the disease was the retreat of blood from the skin, and the want of a sufficient *vis a tergo* for the blood. From this time, therefore, he took care that a warm bath should be at all times kept ready in his regiment's quarters; and the instant a man was seized with signs of plague, he was put in it, and kept there—wine, ether, or some other stimulant, being at the same time administered—till perspiration came on. By these means he never after lost a patient; but he was bound to say he did not begin to use them till the disease was on the decline. He would also mention, that if there was sufficient strength in the system, or sufficient *vis a tergo* for suppuration to take place in the buboes, the patients never died. Their recovery was equally sure when their system could be affected, though but slightly, with mercury.

Dr. James Johnson said, the only mode of reconciling the opposed statements of the advocates for and against contagion, was by supposing that they had seen the plague under different circumstances. One person, for instance, might see it exclusively in those places where it had arisen, and was maintained, by peculiar epidemic conditions; another might see it only where it had been conveyed from the place of its origin, and was propagated by contagion. It was nothing strange that a disease should commence in one method, and be propagated by another; that having originated as an epidemic, it should be propagated by contagion. No one could deny the contagious nature of syphilis; yet it could not have commenced by contagion; the first person who had it must have had it engendered in him by some cause altogether independent of contagion. And the same was probably true of plague and many other diseases.

Dr. Addison said that there was not one of the arguments adduced against the contagiousness of plague which might not equally be applied to any other of the analogous diseases which were universally admitted to be contagious. The immunity which any person enjoyed when placed amongst those dying of plague was no proof that it was not contagious. Several persons were known to have a similar immunity from small-pox, measles, typhus fever, &c. : and there were some who seemed to be proof against all the diseases by which others were ordinarily affected. The fact that Mr. Davis had not had the plague, was strong evidence that he enjoyed a peculiar incapability of receiving the disease ; for independently of contagion, the fatiguing service in which he was engaged might have been expected to render him very susceptible to the disease, from whatever source it might arise. As to the plague prevailing at particular seasons, that also was a character common to all the contagious diseases ; it was by no means essential that they should rage at all times. The same might be said of locality and other circumstances favouring its spread. The most strenuous defenders of contagion would not pretend that it was altogether independent of external conditions. In typhus fever, for instance, which was perhaps of all the diseases of this country the most nearly analogous to plague, this fact of its dependence for its degree of contagion upon external circumstances was often strikingly shown. He was aware that there were differences of opinion respecting the contagious nature of this disease, but he thought it was every year becoming the general opinion throughout the kingdom that, under certain circumstances at least, it was contagious. The chief of these circumstances were, poverty, the absence of the necessary precautions for ventilations, and the crowding of patients together in small spaces. This was often shown in hospitals. Dr. Marcet once, being anxious, in the beginning of his course of lectures, to illustrate the subject of typhus fever, collected together a number of cases in one of the wards. The consequence was, that though previously cases of typhus were admitted with impunity into the wards, and never spread either to their attendants or to other patients, now, when the ward contained few besides the fever patients, some of those few, and several of the nurses, and others, took the disease ; nor did it cease to spread till the cases were again distributed through the different wards of the hospital. The case (and there were many others like it) was the more important as proving the evil consequences of establishing hospitals for the admission of fever patients only, or for any class of contagious diseases. The history of the London Fever

Hospital afforded abundant proof not only of the contagious nature of typhus, but of the ill consequences of bringing together a crowd of patients affected with it. Scarcely a person in that establishment had escaped having fever ; whereas in ordinary hospitals it was only very rarely that the disease spread either to the other patients or to the attendants.

Mr. Hawkins would mention one fact to illustrate how difficult it is to obtain complete evidence in questions of this kind. When he was a lecturer on anatomy, six of his pupils, all residing in different parts of London, were at one time seized with small-pox, yet none of them had any idea where he had been exposed to the contagion. The fact was, a body of a person who had died of small-pox had been brought for dissection, and he had had it put in a room through which these among other pupils had occasion to pass. None of them, however, knew of the body being there, and two of them had only once passed through the room in which it lay. One of them in passing through felt a distinct rigor, and became ill almost directly afterwards ; but had it not been that he was himself acquainted with the common source of the contagion which afflicted them all, all these persons would certainly have referred their disease to some wrong cause. He had little doubt that in many cases similarly imperfect observations were made the basis of conclusions regarding the contagiousness and non-contagiousness of diseases.

Dr. Truman spoke in favour of the maintenance of the quarantine laws, which he thought were now more than ever necessary, when the passage from infected countries was made so much more rapidly by steam than it had ever before been. The very circumstance of there being a difference of opinion respecting the contagion of the plague was sufficient evidence of the necessity of caution. There were, no doubt, defects in them, but it would be better to remedy these than to do away with the laws altogether.

Dr. Gregory said, the arguments used against the contagion of the plague would exactly apply, *mutatis mutandis*, to the small-pox. When the French hospitals, in 1839, contained numerous cases of small-pox, and it did not spread to patients lying in the same wards, the non-contagionist might say there was evidence there that the disease never spread by contact ; and now, when there was hardly a case of small-pox in London, he might in the same way urge the absurdity of thinking the disease contagious when it had almost ceased to be communicated. At present, of the three or four cases in the Small-pox Hospital, not one had communicated the disease

to any other member of his family. All these were circumstances similar to those by which the opinion that the plague is not contagious were supported; yet surely no one would on such grounds as these deny that small-pox is contagious, when thousands of facts, on the other side, prove that it really spreads by contact.

Dr. Webster, Mr. Arnott, and Dr. Weatherhead, spoke briefly in favour of the doctrine of non-contagion, and of the propriety of abrogating the quarantine laws, their chief argument being that a truly contagious disease could not have remained so long limited to a particular region.

### THE MEDICAL ASSOCIATION OF THE NORTH OF ENGLAND.

THE annual meeting of this institution was held on Tuesday last, in the lecture-room of the Literary and Philosophical Society, Newcastle-upon-Tyne. There was a large attendance of the members, and there were also several non-professional gentlemen present; the meetings of the North of England Medical Association being open to the public.

Dr. Headlam, the President, having taken the chair, addressed the meeting in a neat speech, in which he congratulated the members on the flourishing state of their association. He then proceeded to speak of medical reform, and expressed his fears that the Bill of Sir James Graham would not be all that could be desired. He apprehended that the mover was too much under the influence of the corporate bodies. But, continued he, "let the subject be once brought fairly and authoritatively before Parliament, and a full discussion take place, and a measure founded on truth and justice must prevail."

Mr. C. T. Carter, Hon. Secretary, read the Report of the Council, as follows:—

The council, in presenting a report of their proceedings during the past year, have sincere pleasure in being able to congratulate the members of the North of England Medical Association on its prosperity, and on the steady support of the profession which it continues to receive. They hope that the statement they have now to submit to this meeting, will show that they have not been unmindful of the trust confided to them, and that during their term of office they have been anxious to promote, to the utmost of their power, the several designs for which the Society was established; and, in particular, that the primary object of the Association—namely, that of cooperating with other professional bodies in the endeavour to obtain an amendment in the laws and institutions connected with the medical profession in Great Britain and Ireland—has not been

disregarded. The Council have taken every opportunity of advocating the claims of the profession to the notice both of the government and the legislature.

The Report adopted at the anniversary meeting held in April, 1841, was printed and extensively circulated. The petitions in favour of medical reform, and for an amendment of the system of parochial medical relief, were duly presented to the House of Commons; all the members of Parliament connected with the counties of Northumberland, Durham, and Cumberland, and several others, having at the same time been requested to support the prayer of these petitions.

The circumstances attendant on the close of the session of parliament in June, 1841, having precluded the consideration of medical affairs by that parliament, the Council urged the members of the Association to impress upon candidates at the general election the importance of medical reform, as a question involving the welfare, not of the medical profession alone, but of society at large. They have reason to believe that many of our legislators are now alive to the importance of the subject. Many have pledged themselves to give it their serious consideration; and there is ground for hope, that when again introduced to the notice of parliament, it will not fail to meet with an adequate degree of attention.

The Medical Reform Bills which were promulgated during the last two years having been laid aside, your Council, unwilling that any relaxation should take place in the efforts of the reforming part of the profession, and desirous to gather as clearly as possible the sentiments of the Association upon the details of a plan for the better regulation of medical affairs, appointed, in the month of June, a Committee to consider the different plans which had been already produced, and to lay before the Council such suggestions as might occur to them in connection with their inquiry. After due consideration, the committee deemed it advisable to submit two outlines of plans; and upon the respective merits of these, the Council were desirous to take the sense of the members at their general meeting held at Durham in October last. The outlines were printed in the circulars which were sent to members previously to that meeting. It was, however, considered by the meeting unnecessary to decide upon them at that time; and recent circumstances, which will be more particularly adverted to in another part of this report, have arisen to obviate the necessity of bringing the plans under review at the present meeting.

In the month of July, Dr. Brown, of Sunderland, and Dr. Charlton, of Newcastle, were appointed a deputation to meet the

Provincial Medical and Surgical Association at York. The latter gentleman was prevented attending by a severe and protracted illness. Dr. Brown gave his support to the reform measures advocated by that association, and urged the propriety of a full and free cooperation of the different associated bodies, in furtherance of their efforts to obtain for the United Kingdom an amended system of medical polity. The unanimous thanks of the Council were given to Dr. Brown for his services.

At the general meeting in October a copious report was read of the transactions of the Council since their appointment in the month of April preceding. In this document, various points, illustrative of the existing state of the profession, were discussed. Other business of considerable interest occupied the attention of the meeting. A motion was made relative to the admission of non-medical gentlemen as honorary members of the association; a committee was nominated to report on the present mode of appointing medical and surgical officers to hospitals and other public charities; and a petition relative to certain alleged defects in the anatomy act was referred to the Council.

No steps have hitherto been taken in reference to the last of these subjects,—circumstances having arisen to induce a belief that the principal grounds of the complaint stated in the petition were likely to be removed. Should such, however, not be the case, the question might (with the sanction of this meeting) be again considered by the Council.

The propriety of admitting non-medical gentlemen as *honorary* members of the association has been discussed, and the *principle* of such admission acquiesced in by the Council. The regulations under which it would be proper to admit lay members have not been decided by the Council, and their further consideration will depend on the course which this meeting may think proper to take in regard to the proposition.

In the month of January, your Council prepared a memorial to the Secretary of State for the Home Department, relative to the present state of the medical profession—300 copies of which were printed for circulation. The memorial was transmitted to Mr. Hodgson Hinde, M.P. who, at the request of the Council, obligingly consented to place it in the hands of Sir James Graham.

As on former occasions, so also on the present, the Council have to state that, agreeably with one of the fundamental principles of the association, an active correspondence has been carried on, throughout the past year, with various medical associations, as well as with other parties who take an interest in medical reform. Amongst these may be mentioned the names of Dr. Kidd,

of Oxford; Mr. Carmichael, of Dublin; Dr. Barlow, of Bath; Dr. Hastings, of Worcester; Mr. W. Wood, of Edinburgh; Dr. Webster, of Dulwich; Mr. Ceely, of Aylesbury; Dr. Jeffreys, of Liverpool, &c. &c.

The Council have been glad to perceive, within the last few days, some indications of improvement in the system of Poor-Law medical relief. The Commissioners have lately issued a 'medical order,' the main features of which consist in the fixing a maximum of area and population for districts, and the institution of a permanent pauper list. The medical attendants are to hold office *permanently* instead of *annually*, and are to possess a double qualification in medicine and surgery. The system of "tender" is to be abolished, and an extra remuneration allowed for surgical operations and midwifery. The 'order' is of too recent date to admit of the Council giving an opinion upon its several heads in this Report. They would beg, however, to remark, that in defining the qualification of the medical officers, an unjust restriction has been placed on the graduates of Scotch and Irish Universities, and on the members of the Colleges of Surgeons of Edinburgh and Dublin.

After the strenuous exertions made in the cause of medical reform within the last few years, by a large proportion at least of the profession, it cannot be otherwise than gratifying to this and other kindred associations, to know that the subject has at length attracted the attention of Government. During the early part of the present session of Parliament, Sir James Graham, as numbers are well aware, announced his intention to bring into the House of Commons a Bill for the better government of the medical profession. The Council are not provided with an outline of the proposed measure, but the bare announcement that a medical bill is likely, at no distant period of time, to be introduced into the legislature by a minister of the Crown, affords a gratifying proof that the importance of the question of medical reform has been recognized in the proper quarter, and should act as a great encouragement to those parties who have toiled in the cause, to continue their efforts, showing, as it does, that their past exertions have been neither visionary nor fruitless.

The contents of the anticipated Bill have not yet been made known to the profession, although the heads of it are said to have been communicated to the authorities of the Colleges of Physicians and Surgeons of London. The Council are consequently not prepared to lay before this meeting any definite information respecting it. Rumours as to its provisions are not, however, wanting; and as these have, in certain quarters, been made with considerable confidence, they

must not be allowed to pass entirely unnoticed in this Report. The Council hope, at the same time, that the result may prove the said rumours to have been somewhat premature, and not altogether correct, and that a measure so little in accordance with the feelings and wishes of nearly the whole professional body, and of such questionable efficacy as regards the well-being of the community, as report has attributed to Sir James Graham, may not be brought into Parliament with the sanction of her Majesty's Government.

It is not to be supposed that a plan of medical reform can be acceptable to the profession which would concentrate the whole governing power of that profession (for England at least) in the Colleges of Physicians and Surgeons of London, even with such alterations in the constitution of those bodies as have been hinted at in connection with the reported arrangements. The well-earned unpopularity of these Colleges, their indifference to the general welfare of the profession, must be known to the Right Honourable Secretary for the Home Department, who was a member of Mr. Warburton's Committee on Medical Education, &c., in 1834; and surely it cannot be intended that they *alone* should furnish the elements out of which is to be constructed a Central Board or Council of Health; whilst the mass of English medical men—the general practitioners of the kingdom—are to have no voice in the election of a body to which is to be entrusted the entire management and control of medical affairs. Neither is it to be imagined that this numerous class will be contented that the licensing power—the power which gives them a legal recognition as practitioners of medicine—should be held by a corporation which is not deemed worthy to form a constituent part of the General Board of Management. If report be deserving of credit, the triple examination which, consistently therewith, the general practitioner is to undergo, by *physicians, surgeons, and apothecaries*, and the threefold nature of his professional duties, instead of entitling him to consideration, would be made the ground of his exclusion from all participation in the election of the General Council—this privilege being confined to those who *profess* to limit their practice exclusively to medicine or to surgery. The plan (as reported) does not aim at preserving that natural unity of the profession which has been so universally acknowledged in modern times. The most eminent members of the profession have agreed, that, up to a certain point (and that the commencement of their practical career), the education of the physician and the surgeon should be the same. No one will, in these days, be found to deny that the physician, although rarely

or never required to perform the *manual* operations of the healing art, should nevertheless understand both the theory and practice of surgery; and a knowledge of medicine is even still more indispensable to the surgeon, for it is notorious that the greater part of the practice of those persons who are designated pure or consulting surgeons, is in medical cases, and no man unskilled in medicine can hope to treat with success those diseases which are usually consigned to the surgeon: and yet, according to the reported ministerial plan of medical reform, no provision seems to exist for testing the medical knowledge of the surgical practitioner.

The inadequately protected condition of the qualified medical practitioner has long been a cause of complaint. His title has been usurped, his privileges have been trenched upon with impunity; and such is the anomalous state of medical government in this country, that whilst the impostor is allowed to reap an abundant harvest, the educated physician is unable to recover at law his charge for professional attendance. The protection now enjoyed by the licensed general practitioner, feeble and inefficient though it be, is to be exchanged, according to the reported Bill, for a mere *discouragement* of unauthorized practice. Public appointments are to be held only by the qualified members of the profession, and druggists, like physicians, are not to recover at law charges for medical advice.

The Council forbear to pursue this subject in the absence of precise data, and the foregoing observations must be distinctly understood as applying to the outlines of the Bill *imputed* to Sir James Graham by certain of the medical journals, and other portions of the public press. The Council hope that as the measure is not yet completed, and will not, in all probability, be brought forward during the *present* session of Parliament, the Right Honourable Baronet, in attempting to legislate on this momentous but difficult subject, will not permit himself to be swayed by any undue influence, but will summon to his councils parties from whom he is likely to receive a disinterested statement of the actual condition of medical affairs, and with whose assistance he may expect to frame a Bill which shall satisfy the reasonable demands of medical men, and be productive of beneficial consequences to the entire population of this great empire.

In the meantime, members of the profession must be vigilant and active; and in order to meet any emergency which may arise during the ensuing twelvemonth, your council have to recommend that this meeting do authorize their successors in office to act as circumstances shall require, in reference to medical legislation. They would urge the members of the Association, individually, to

impress upon members of Parliament the principles of reform which have been advocated by this and other associated bodies, and which have been approved and supported by some of the most distinguished ornaments of the profession: the principles, namely, of—1. A full and fair representation of the professional body in the government of the medical corporation, and in the appointment of the medical members of any general board or council which may hereafter be formed. 2. A uniform qualification as the requisite for a license to practise medicine, to which branch of it soever the licentiate may more *especially* direct his attention, and irrespective of any degree or title which he may desire to possess. 3. Reciprocal privileges for licensed practitioners throughout England, Scotland, and Ireland. 4. A protective power, both for the public and the profession, against spurious and unauthorized practitioners of medicine or surgery.

These principles, as your council have repeatedly endeavoured to explain, could be carried into effect without the abrogation of the existing orders of physician, surgeon, and general practitioner, and without any improper or unwarrantable interference with the rights and privileges of the universities and colleges of the United Kingdom. Their power to educate students, and to grant degrees and diplomas, they would still retain—subject, perhaps, to the control of a general board or council; and it would be most desirable that through the instrumentality of such a council, the conditions attached to the granting of degrees, diplomas, &c. should be assimilated throughout the three countries, so that the same title might indicate a *given* qualification, by whichsoever of the universities or colleges it should have been conferred. The propriety of such an arrangement has been recognized in a report published some time since by the Royal College of Physicians in London.

To obtain an improved system of government for the medical profession, is not by any means the sole object of this Association. The qualification of the legally-recognized practitioner, and the general direction of medical affairs, may be provided for by the State. The *social* well-being of the medical body, the maintenance of its honour and respectability, the promotion of kindly feelings amongst its members, must ever be in the hands of the profession itself. They are comprised in the scheme of this Association, and have not been overlooked by your council, although, from the peculiar position of public affairs, other objects have hitherto engrossed a larger and more conspicuous share of their attention. The comfort and happiness of the individual practitioner must always, in a great measure, depend on the existence of a proper understanding between himself and his professional

neighbours, as to the line of conduct by which they are to be guided in their intercourse with each other; and in a profession the members of which, perhaps, above those of any other, are apt to be thrown into collision, it is most desirable that on this point some clearly-defined principles should prevail, and should, moreover, be strictly observed. By no means can this end be so effectually accomplished as by a union of the practitioners of a given locality into a society or association. Such unions exist, and often with the most salutary consequences, in almost every class of the community: they are eminently deserving the support of medical men. The various ways in which they might be rendered conducive to the common welfare of the latter need not here be enumerated. It has long been the opinion of your council that this Association might be made subservient to their promotion; and in former reports the division of the Association into *sections* was strongly recommended. Under such an arrangement, each section might watch over the local interests of its members; while the interests of the Association as a body, and of the profession at large, would engage the attention of your council, and of members collectively, at their general meetings. The council cannot take their leave without repeating their recommendation in regard to this point; and they are happy to state that immediately subsequent to the last anniversary meeting, the members of the Association resident in Sunderland formed themselves into a section, which has held several meetings during the year.

On referring to the list of members it will be seen that several new and valuable names have been added during the past twelvemonth; but the council are at the same time compelled to express their regret that some of their earliest associates have left the Association, because the benefits which they had been led to expect as likely to result from its labours, have not been realized so speedily as they have desired. These gentlemen should have borne in mind that the purposes for which this Society was called into being are to be accomplished only by unwearied patience, by continued perseverance, by untiring industry. The movement of the Association may to some have appeared slow, and almost imperceptible; but the council are warranted in believing that they have not been wholly unappreciated by their brethren throughout the country. The success of the Association, and the extent of its usefulness, must obviously be commensurate with the degree of support which shall be given it by the medical practitioners of the northern counties of England; and where the individual contribution is almost nominal, it cannot but be a matter both of surprise and concern, that any member of the profession (admissible by its

rules) should withhold his aid from an institution whose designs are so excellent, and whose exertions are unceasingly directed to the fulfilment of noble and praiseworthy objects.

The report was unanimously adopted, after which a vote of thanks to the secretary was moved and passed by acclamation: after this Dr. Glover was called upon to read the report of the Committee on Medical Appointments to Hospitals and other Public Charities.

We can only make room for the conclusion, by which we find that, besides the abolition of canvassing, the only recommendations of the committee are two:—

"1. That the appointment should not be made for life, but for a term of seven years (as in Edinburgh), or other limited period. The appointment should then be renewable, but the office open to competition. Along with this, all the medical officers of infirmaries and dispensaries should be compelled to give clinical instructions where pupils are to be found.

"2. That no one be allowed to hold more than one infirmary and one dispensary appointment together.

"A notion prevails among the public, that the cultivation of medical science in public institutions is in some degree opposed to the welfare of the patients. This prejudice is entertained by people whose position should give them liberality of sentiment. It is clear that the more attention a medical man can be induced to bestow upon a case, and the more his treatment is subject to criticism, so much better will it be, on the whole, for the patient. Besides, the cultivation of medical science in an hospital, and the publication of new facts, may cause a thousand benefits, and lead to the alleviation of human suffering throughout the world, and for ages to come.

"Your committee are of opinion that, in the present stage of the inquiry, they cannot do more than thus report progress, and ask leave to make any communication to the Association which a more matured state of the investigation may render necessary."

After some discussion (a recommendation which the report contained of pure physicians and surgeons to hospitals having been objected to) it was carried by a shew of hands. After this some less important matters were disposed of, and the meeting closed with a vote of thanks to the President. The members afterwards dined together, and the evening passed off in the most satisfactory manner.

On the following day, the voting-papers, delivered at the business-meeting in the lecture-room, were examined by the scrutineers, and the election was found to have fallen on the following gentleman:—

*President.*—Dr. Headlam.

*Vice-Presidents.*—Dr. Brown, Mr. Baird,

Mr. T. M. Greenhow, Dr. Cahill (Berwick), Sir John Fife, Dr. Winterbottom (South Shields), Mr. Green (Durham), and Dr. Elliot (Carlisle).

*Treasurer and Secretary.*—Mr. C. T. Carter.

*Council.*—Dr. Charlton, Mr. Potter, Dr. De Mey, Dr. Knott, Dr. R. Elliot, Dr. Glover, Dr. Embleton, Dr. Cargill, Mr. Bennett, Dr. Fife, Mr. Tulloch, Mr. Dawson, Dr. Oliver, Mr. Dixon (Sunderland), Dr. Whight, Mr. Talmadge, Mr. Brumell, Mr. Mordey (Sunderland), Mr. Dodd (Sunderland), Mr. Gregory (Sunderland), Dr. R. James (Carlisle), Mr. Watson, Mr. W. K. Eddowes (South Shields), and Mr. Sang.

### A TABLE OF MORTALITY FOR THE METROPOLIS,

Shewing the number of deaths from all causes registered in the week ending Saturday, April 16, 1842.

Wind variable, N.E. prevailing.

On the 20th and following day clear.—The 22d, morning overcast, otherwise clear. The 23d, morning and afternoon clear, evening overcast, distant thunder heard in the evening. The 24th, morning clear, otherwise cloudy, lightning and distant thunder, accompanied with rain in the afternoon. The 25th and following day, clear.

Rain fallen, 0.45 of an inch.

LECTURES  
ON THE  
PRINCIPLES AND PRACTICE OF  
PHYSIC,

Delivered at King's College, London,

By DR. WATSON.

LECTURE LXXIII.

*Entozoa continued. Hydatids. Trichina spiralis. The Guinea worm. Strongylus gigas. Origin of Entozoa. Question of spontaneous generation. General symptoms of the presence of intestinal worms. Particular symptoms, and remedies, of the common round worm, of thread-worms, of tape-worms.*

At our last meeting I gave a summary description, sufficient however for our purposes as medical practitioners, of the five kinds of *vermes* which are most common in the human intestinal canal. There are yet a few more of these entozoa which are curious and interesting enough to deserve a brief notice.

*Hydatids*—animals like bags or bladders of water—are of very frequent occurrence in various parts of the body. They are also called *acephalocysts*, headless bags. These are not to be confounded with enlarged graafian or other vesicles, nor with morbid serous cysts in general. They look like, or rather they are, spherical sacs having one aperture only, and containing a thin colourless liquid. They are usually found congregated, sometimes in vast numbers, within a large cavity or cyst, to which they are unattached. This is a consequence of the peculiar manner in which the animals are propagated. The wall of the cyst is laminated, and the young hydatids bud forth from between its layers. In the species which infests the human frame, they are born into the cavity of the parent: in some other

species they are detached externally. We find therefore a parent bag, full of other smaller bags; which, again, are pregnant, as it were, with their own offspring, the grandchildren of the primary cyst: and so on, somewhat after the manner of a nest of pill-boxes. Minute in their origin, these parasites may thus increase and multiply till the original cyst attains an immense size, and at length destroys life by its bulk and pressure. Of course the immediate consequences of such pressure will depend greatly upon the parts occupied by the hydatids. You may readily imagine what kind of symptoms are likely to ensue when they are lodged within the abdomen, within the less yielding thorax, within the unyielding skull. They are more common in the liver than in any other single organ. A woman died recently in the Middlesex Hospital, whose liver contained thousands of these globular bodies. The enlarged gland had completely sealed up, by its pressure, a portion of the inferior cava.

We can seldom tell that hydatids exist in the body until we see them; nor, if we knew of their presence, could we propose any rational method of cure. It has been fancied that a galvanic current, or an electric shock, passed through the organ containing these creatures, might kill them, and so at least prevent their increase: or that they might be poisoned by drugs that are not seriously prejudicial to man, such as mercury or iodine. But these are mere dreams of our baffled art. They sometimes open a way for themselves to the surface; and escape through an ulcerated outlet: and sometimes they are let out, to the surprise perhaps of the operator, who only knew that he was dealing with an abscess which required puncturing. Mr. Arnott put a lancet into a fluctuating tumor in the epigastrium of one of my patients; very offensive pus issued, with the shrivelled skins of sundry defunct hydatids. The cyst was situated, I believe, in the liver. Although the orifice was slow to heal, the patient ultimately got well.

There are single cyst-like bodies, with short retractile necks, bearing the generic name of *cysticercus*. One species of this kind, the *cysticercus cellulose*, inhabits the interfascicular cellular tissue of the muscles. It is rare in the human subject, but frequent in the pig; giving rise to that condition of the muscles which is familiarly known as mealy pork. This is one of the internal parasites with which the organ of vision is liable to be infested. A most remarkable instance occurred a few years ago, in Glasgow. In the eye of a child, who had suffered repeated attacks of ophthalmia, Mr. Logan discovered one day, to his extreme astonishment, a semitransparent body, about two lines in diameter, floating unattached in the anterior chamber. It seemed almost perfectly spherical, except that from its lower edge there proceeded a slender process, of a white colour, with a slightly bulbous extremity, which appeared to be heavier than the globular part, for it was always turned downwards. This head, or neck, was seen to project or elongate itself from time to time; and occasionally it was drawn up and completely hidden in the cystic portion. When the patient sat still, in a moderate light, the animal covered the two lower thirds of the pupil. "Watching it carefully (says the gentleman who has recorded the case), its cystic portion was seen to become more or less spherical, and then to assume a flattened form; while its head I saw at one moment thrust suddenly down to the bottom of the anterior chamber, and at the next drawn up so completely as to be scarcely visible." The child's head was now turned gently back, and instantly the hydatid revolved through the aqueous humour, so that its head fell to the upper edge of the cornea, now the more depending part. Upon the child again leaning forwards, it settled, like a little balloon, in its former position; preventing the patient from seeing objects directly before her.

The animal was carefully watched for three weeks; and no other change was noticed than a slight increase in the bulk of its cystic portion. In six weeks it had evidently grown bigger, the eye become injected, and the iris less free in its movements; and pain ensued. Extraction of the hydatid was attempted; but the patient was unruly; the lens was forced out, and the animal ruptured and expelled in shreds: the iris became entangled in the wound of the cornea, and vision in that eye was spoiled.

There is a very singular microscopic parasite, the *trichina spiralis*, dwelling in myriads, sometimes, in the muscles of the living human body. It was first described by Professor Owen in 1835. Mr. Wormald, the Demonstrator of Anatomy at St. Bar-

tholomew's Hospital, sent to that gentleman a portion of human muscle, which presented a singular speckled appearance, as if it were mouldy. Mr. Owen found that each speck was a shuttle-shaped cyst, containing a very minute cylindrical worm, coiled up in two, or two and a half, spiral turns. The worm measures, when unrolled, no more than  $\frac{1}{10}$  of an inch in length, and  $\frac{1}{80}$  of an inch in diameter; and of course requires, for a satisfactory examination, to be seen through a microscope. The longer axis of the containing cyst lies between, and parallel to, the fibres of the muscle. Fourteen similar instances have since come to Mr. Owen's knowledge.

This is a very strange kind of parasite. One would imagine that the presence of innumerable living beings, in or between the muscular fibres, would be likely to give rise to symptoms. We might expect pain, or muscular debility, or embarrassed movements; yet no indication of the presence of these worms seems to have been afforded in those instances in which the condition of the subject in whom they were found was known, during life. The principal points that have hitherto been made out appear to be the following:—

1. The muscles thus beset with parasites are the voluntary muscles: and those which lie superficially are fuller of the worm than the deeper seated. The pectoralis major, latissimus dorsi, and other large flat muscles, usually present them in great abundance. They have been detected in the muscles of the eye; and even in those belonging to the little bones of the ear, and of whose actions we are wholly unconscious. They occur also in the diaphragm, in the muscles of the tongue and of the larynx, in those of the soft palate, in the constrictors of the pharynx, in the levator ani, in the external sphincter ani, and in the muscles of the urethra. They have not yet been seen in the muscular tunic of the stomach and intestines, in the detrusor urinæ, or in the heart. Mr. Owen makes this interesting remark—that all the muscles infested by the trichina are characterized by the striated appearance of their ultimate fasciculi: whereas the muscles of organic life, which the animal does not inhabit, have, with the exception of the heart, smooth fibres, not grouped into fasciculi, but united reticularly.

2. It appears, also, from what has been hitherto observed of these entozoa, that their presence in the body is unconnected with age, sex, or any particular form of disease. They have been concomitant with cancer of the penis, tubercles of the lungs, exhaustion of the vital powers by extensive ulceration of the leg, fever combined with pulmonary phthisis, aneurism of the aorta, sudden depression or collapse after a comminuted

fracture of the humerus, diarrhoea. They have also been met with in the muscles of a man who, while in the apparent enjoyment of robust health, was killed by a fracture of the skull.

The *Filaria Medinensis*—*Dracunculus*—or *Guinea-worm*—has its residence in the subcutaneous cellular tissue. It is a long, slender, round, uniform animal, like a fiddle-string, or a piece of bobbin; as you may see in the specimens before you. Its length varies from five or six inches to twice as many feet. Men's lower limbs, their feet and legs, are the parts most commonly possessed by this worm; but it occurs also in the scrotum, in the parietes of the belly, in the arms, beneath the conjunctiva of the eye, and in almost every superficial situation. It is sometimes solitary; but several may coexist or succeed each other in the same individual; nine or ten perhaps. A Dr. Marradri, a friend of the celebrated Clot Bey, had suffered from 28 of them in succession.

This entozoon is endemic in the hot inter-tropical regions; in Asia and Africa; upon the coast of *Guinea*, whence its trivial name. It sometimes abounds after the manner of an epidemic. Sir James M'Grigor tells us that the 86th and the 88th regiments, stationed at Bombay, were much plagued by this pest. The 86th was free from it upon entering the fort, in September 1799; and so continued till the setting in of the monsoon in 1800. In the course of the monsoon nearly 300 of the men were attacked. The 88th regiment relieved the 86th. No case of Guinea-worm appeared among them for nearly a month after their coming into the barracks in Bombay, in October, 1800. In the latter end of November, they embarked for the Egyptian expedition; and in the course of the voyage, in one ship alone 199 men out of 360 were crippled and laid up with this loathsome disease. It was thought to be infectious. The artillery-men, who were kept separate, escaped. Of 181 instances, of which Sir James M'Grigor gives a tabular account, the feet were the parts affected in 124.

These animals sometimes remain for a long while in the cellular tissue without producing inconvenience, and therefore without betraying their presence. Hence they are sometimes brought over to this country. The great navigator, Dampier, had no symptom of a Guinea-worm which he carried about with him, until about half a year after he left the place in which he contracted it. Sometimes the parasite is quiet and harmless for a still longer period; in one recorded instance it was latent and dormant for three years.

The symptoms which do at length arise are the following: itching of the part affected; a sensation as if there were some-

thing creeping under the skin; sometimes a cord-like ridge can be felt in the track of the worm: at length a vesicle, or a pustule, or a little boil forms, from which, when it breaks, the head of the animal protrudes. This process is often attended with fever; and in certain parts of the body the local suffering is considerable: the cellular tissue sloughs; and sometimes dangerous hæmorrhage occurs.

The only treatment which these cases appear to admit of, is the gradual and careful extraction of the worm. Lest that part of it which already protrudes should recede, or be broken, it is gently wound, day by day, round a small stick, or a little roll of adhesive plaster; pains being taken not to pull upon it so much as to risk its being torn asunder. The roll is protected by a bandage. Whenever, by accident, the animal is broken, very serious consequences are said to ensue; violent inflammation of the part, abscesses and sinuses, and high irritative fever. This mischief is ascribed by some to the presence of dead animal matter, by others, of young filarise, in the subcutaneous tissue: for I should have mentioned that the Guinea-worm is viviparous; and although neither digestive organs nor generative organs have yet been discovered in its structure, it is sometimes found stuffed internally with a countless offspring. The extraction is tedious work. Where, indeed, the cellular tissue is very loose, as in the scrotum, the worm is occasionally drawn out at the first attempt: but the process sometimes occupies weeks; and its average period appears to be not less than ten days. When the course of the animal is quite superficial and obvious, the natives are accustomed to make an incision in the skin, at about the middle point, and to pull the worm through from both ends. When once it is out, the parts presently heal. All other medication (and much has been tried) has been found useless; except, perhaps, the administration of assafoetida: and that not as a means of cure, but of prevention. It is said that the Brahmins in India, who are in the constant habit of using this drug, are exempt from attacks of the dracunculus. Cleanliness was also found, in the army, to be a considerable protection.

There is a species of filaria peculiar to the eye; and another to the bronchial glands: but these are extremely rare.

The urinary organs have their parasites also: of which I shall specify but one, and that chiefly on account of its strange lurking-place, and remarkable size. I allude to a species of strongle which sometimes occupies the human kidney, and which is no uncommon tenant of the same organ in various animals; the horse, the bull, the dog, the wolf, the polecat, and the otter. In the

human subject its length varies between five inches and a yard, and it is sometimes half an inch in diameter. There is a specimen nearly of that size in the Hunterian museum. It may well be called the *giant* strongle, *strongulus gigas*. Fancy a creature as big as a snake coiled up in one's kidney. It gives rise to no distinctive symptoms, although, as you may suppose, it causes much renal distress; hæmaturia, retention of urine, and great suffering in its passage out of the body, either through the natural urinary channels; or by abscess and ulceration through the back.

With respect to some, at least, of the parasitic animals that I have been describing, those I mean which are found shut up in close chambers, our first feeling is that of wonder how they came there. Into all parts from which a road is open to the external surface, we can conceive that living creatures may enter, or their eggs be carried. But how can either animals or ova find their way, unperceived, into the substance of the liver and of the voluntary muscles, into the eye, into the brain? The whole matter is obscure, yet interesting.

It was the opinion of Linnæus, and of other natural philosophers of his time, that the *intestinal* worms were really terrestrial or aquatic animals which had been accidentally swallowed, either while young and small, or in the antecedent state of ova. It was even pretended that these animals had been recognized and detected out of the body, in stagnant waters. But later enquirers, especially Bremser and Rudolphi, have completely disproved this notion. After dedicating twelve years of his life to the observation and study of entozoa, Bremser was satisfied that no creatures identical in structure with the intestinal worms are ever met with out of the body, except such as have come from the intestines of man, or of some other animal: and conversely, that no terrestrial or aquatic worms are ever found living within the bodies of men or of animals, unless they have been directly and plainly received from without.

But, then, is it not possible that, as Boerhaave supposed, aquatic or terrestrial reptiles, casually entering the body from without, being placed under entirely new and unnatural conditions, may have attained a monstrous growth, and undergone metamorphoses such as we know that some of the lower animals, by change of circumstance, do undergo; as the tadpole becomes a frog, the maggot a butterfly?

To the reception of this theory there are strong grounds of objection. First, there is no ascertained relation (as in the other cases) between the structure of intestinal worms, and of animals having an independent ex-

istence out of the body: and they are never caught (as they would surely sometimes be) in the transition state—the intermediate condition. Secondly, opposed to this “accidental” hypothesis are also the facts that certain species of worms infest certain species of animals only: that in the same animal different species of worms occupy (as we have seen) special parts of the alimentary canal; have each their peculiar habitat: that worms and animals of external origin mostly die as soon as they are received into the digestive organs; while the true intestinal worms perish whenever they are delivered therefrom. Thirdly, the circumstances that these worms not only live but breed within the human bowels, and that they are met with even in the intestines of the unborn foetus, are very adverse to this theory of an accidental *error loci*.

But, to give up the notion of a metamorphosis, may not intestinal worms spring from specific germs or ova introduced from without, not casually, but in accordance with a natural law: germs or ova which find in the interior of living bodies the only conditions that admit of their development, the only soil in which they are capable of germinating, the only nest in which they can be hatched? I confess that such is my own belief. We have something like this at least in that common affection of horses called the “bots.” A species of æstrus or gadfly deposits its eggs upon the animal's hide, where they cause, I presume, some irritation, which induces the horse to lick that part with his tongue. The eggs are thus conveyed into the mouth, whence they reach the stomach. There they are converted into larvæ, and affix themselves to the parietes of the stomach. At length, when they are ready to undergo their final metamorphosis, they are detached from the interior of the stomach, pass along with the food and fæces through the intestines, and are ejected from the rectum with the dung.

Why, it is asked, may not similar phenomena take place in the human body? There can be no doubt that we every day swallow, inadvertently, numerous ova, of various kinds. It is supposeable enough that sometimes the digestive organs may, and sometimes they may not, have the power of decomposing or expelling these ova.

It is quite certain that what are generally called *spurious* worms may have that mode of origin in the body. Thus, Dr. Elliotson states that he had once a patient, an infant, who discharged from the bowels a dozen live larvæ, or maggots, of the common fly. The child had eaten part of a *high* pheasant some months before. This circumstance was instructive in that case. The infant had been suffering under a chronic cough, but as

soon as those larvæ were got rid of, the cough ceased. Dr. Elliotson says that he saw them in the napkin, moving about in the fæcal matter, just as they might have done if they had never been in the child's body. The same physician tells us that he has twice known, in two different patients of his, a living caterpillar to be discharged from the intestines. One of the patients was a woman who had been in the habit of eating cabbage stalks while she was washing them for the pot. The moth lays its eggs on cabbages, and she no doubt had swallowed some of them, and one had hatched within her. In the ninth volume of Dr. Duncan's *Medical Commentaries* is a precisely similar case. A boy, after a dose or two of calomel and jalap, discharged from the rectum very many caterpillars, all alive, and full of activity. He had been in the habit, when in the garden, of eating young cabbage leaves. Till this habit began he had enjoyed good health. While the animals were within his bowels he suffered severely; had locked jaw; and fell into a state resembling coma. Upon their expulsion he recovered perfectly. Centipedes have in like manner been vomited, and voided from the bowels. But the most wonderful instance of this kind that ever was heard of, is related by Dr. Pickells in the *Transactions of the King and Queen's College of Physicians in Ireland*. A young woman, of melancholic disposition and chlorotic appearance, had been in the daily habit, from some superstitious motive, of drinking water mixed with clay taken from the graves of two priests who lived and died in the odour of sanctity. In this way she probably imbibed the ova of the insects which subsequently issued from her body. In about three years and a quarter, she discharged, partly by vomiting, but chiefly *per anum*, upwards of 2000 beetles, and their larvæ, most of them alive. Dr. Pickells counted more than 1300. Larvæ, and pupæ, and perfect insects, all came forth simultaneously. Some of them ran off, as soon as they were vomited, into holes in the floor; and two large-winged insects were so lively and vigorous, as immediately to fly away. These strange births were preceded and attended by a complicated and distressing train of symptoms; a gnawing, and sense of something creeping at the pit of the stomach, vomiting of blood, amenorrhœa, hysterical convulsions, headache, retention of urine, and sometimes a degree of mental derangement. She was at length freed from this disgusting malady by large doses of the oil of turpentine.

These spurious worms differ from the true intestinal parasites in this—that the human alimentary canal is not their *only*, but their accidental and unusual nidus. Nevertheless, their occasional presence, alive, in that place,

adds to the probability that some of the entozoa may be originally ectozoa.

The main difficulty, however, respects those animals which occupy shut cavities within us, or are imbedded in our solid organs: and this difficulty forms one avowed ground of the theory of *equivocal generation*; which means the spontaneous production of living creatures, independently of any germ, or egg, or parent. The vulgar suppose that dirt engenders fleas, that maggots result from the putrefaction of flesh, that eels arise, of themselves, in and out of mud. In other words, they infer the spontaneous origin of those creatures, of which they cannot or do not trace the procreation by pre-existing parents: and philosophers and men of science have done the same. They will not believe that which they cannot see. Now this doctrine of equivocal generation shocks, I confess, my mind, and offends my reason. If well founded, it strikes at the root of that great argument of Natural Theology, which deduces the existence of a First Intelligent Cause, from the marks of adaptation, design, and contrivance, so manifest throughout the visible universe. Observe the demand which this doctrine makes upon our faith. In defiance of all experience and analogy in respect to creatures which our finite senses are competent to examine, it calls upon us to believe that living beings of complex and intricate, yet definite and harmonious structure; provided with a digestive apparatus, with instruments of locomotion, with generative organs; of various species; in many instances of separate yet answering sexes; that not one or two of these beings, nor a pair or two, but beings and pairs innumerable, are daily formed by the blind concurrence of "organic molecules." The obscurity that hangs over the origin of the entozoa is not indeed the only, nor I think the chief ground upon which the notion of spontaneous generation rests. You are probably aware that minute animalcules, so minute that most of them cannot be seen without a microscope, soon become abundant in water wherein vegetable or animal matters have been dissolved by infusion. Such animalcules are therefore called *Infusoria*. How do they come there? There are two suppositions open to us. One is, that they are formed by the fortuitous union of organic atoms contained in the infusion. The other is, that they proceed from ova or germs existing in the liquid, or floating always in the atmosphere, and ready to quicken whenever they light upon their proper element. That the ova of animals which are themselves visible only by the aid of a microscope, should be absolutely invisible by us, is not surprising. We may conclude that the latter supposition is the most true, if we can show that when these ova or

germs are excluded, all the other conditions of the production of infusoria being present, no animalcules appear. Now Spallanzani long ago found, by careful trials, that no animalcules were discoverable when the access of air to the infusion was completely prevented. But it has been objected to his experiments, that the presence of atmospheric air may be one of the essential conditions upon which the requisite combination of the organic molecules depends. Air, solar light and heat, and organic matters in solution being given—does animal (or even vegetable) life ever result? That is the question. The experimentum crucis has been made, and has answered “no,” as I have lately learned from one of Professor Owen’s admirable introductory lectures; by whom, I am glad to find, this uncomfortable doctrine of equivocal generation is strongly discountenanced. The experiment to which I refer was conducted by M. Schulze, of Berlin. I will read you his own account of it, as I find it recorded in the *Edinburgh New Philosophical Journal*.

“The difficulty to be overcome consisted in the necessity of being assured, first, that at the beginning of the experiment there was no animal or germ capable of development in the infusion; and secondly, that the admitted air contained nothing of the kind. For this purpose I filled a glass flask half full of distilled water, in which I mixed various animal and vegetable substances; I then closed it with a good cork, through which I passed two glass tubes bent at right angles, the whole being air-tight. It was next placed in a sand-bath, and heated until the water boiled violently, and thus all parts had reached a temperature of  $212^{\circ}$ . While the watery vapour was escaping by the glass tubes, I fastened at each end an apparatus which chemists employ for collecting carbonic acid; that to the left was filled with concentrated sulphuric acid, and the other with a solution of potash. By means of the boiling heat, every thing living, and all germs in the flask or in the tubes, were destroyed; and all access was cut off by the sulphuric acid on the one side, and by the potash on the other. I placed this easily moved apparatus before my window, where it was exposed to the action of light, and also, (as I performed my experiment during the summer) to that of heat. At the same time I placed near it an open vessel, with the same substances that had been introduced into the flask, and also after having subjected them to a boiling temperature. In order now to renew constantly the air within the flask, I sucked with my mouth, several times a day, the open end of the apparatus filled with solution of potash; by which process the air entered my mouth from the flask through the caustic liquid, and the atmospheric air

from without entered the flask through the sulphuric acid. The air was of course not at all altered in its composition by passing through the sulphuric acid in the flask, but if sufficient time was allowed for the passage, all the portions of living matter, or of matter capable of becoming animated, were taken up by the sulphuric acid and destroyed. From the 28th of May till the beginning of August, I continued uninterruptedly the renewal of the air in the flask, without being able, by the aid of the microscope, to perceive any living animal or vegetable substance, although during the whole of the time I made my observations almost daily on the edge of the liquid: and when at last I separated the different parts of the apparatus, I could not find in the whole liquid the slightest trace of infusoria, of confervæ, or of mould. But all three presented themselves in great abundance a few days after I had left the flask standing open. The vessel which I placed near the apparatus contained, on the following day, vibriones and monads, to which were soon added larger polygastric infusoria, and afterwards rotatoriae.”

This experiment confirms the belief which various other facts had suggested—that the different kinds of entozoa are not parentless animals, and that they somehow find their way into the body they inhabit from without. The lowest of the infusoria are of fixed and determinate species; and Ehrenberg states that even the minutest monads possess a complicated organization. It may be asked, concerning both them and the entozoa, why, if they ever arise spontaneously, should they be furnished with a generative apparatus? Again, some of the entozoa abound in certain places, and strangers coming to those places appear to contract them there. The dracunculus was thought by the soldiers in India to be communicable from person to person, as the itch insect, and the chigoe, to both of which it has some analogy, certainly are. The infant filaria probably creeps in through the skin without causing any noticeable pain. Even that monster among the entozoa, the tape-worm, invades the bodies of those persons who visit the countries to which it belongs. I told you before that, when tape-worm occurs in Germany, it is almost always the *tænia solium*; when in Switzerland, almost always the *tænia lata*. Now the celebrated Soemmering was afflicted by one of these beasts; and he was by birth a German: yet the worm that he voided was of the foreign species, the *tænia lata*. He had resided, however, for some time in Switzerland; and there, we can scarcely doubt, he caught the ovum, or the young one, of the parasitic animal. Mr. Abernethy once told me the following curious story:—A shepherd had to drive a flock of healthy sheep to a distant part of the

country. The journey occupied two or three days. On the road one of the animals broke its leg, and was carried the rest of the way on horseback. All the flock, except this hurt individual, was turned for one night into a marshy pasture. The broken limb was set, and the patient got well; and was the only one of the whole flock that did not subsequently become affected with the rot; the only one that escaped having flukes in its liver. Is it not presumable that the ova of these parasites were swallowed with the herbage cropped by the sheep in the damp meadow? The germs of the entozoa which dwell in closed chambers, and within the solid viscera of the body, are probably carried thither by the blood.

Upon the whole, we may reject the hypothesis of equivocal generation, and fall back upon the Harveian axiom, taken in its most extended sense, of *omne vivum ex ovo*. If I have digressed somewhat in order to set before you the grounds of my own belief in this matter, the interest and importance of the subject must be my excuse.

What I have further to say will relate exclusively to the intestinal worms of the human body: their predisposing causes; the symptoms they occasion; and the modes of getting rid of them.

However much we may be in the dark as to the exact mode in which these parasites reach their habitations, we do know *something* of the circumstances that appear to favour their production and multiplication. They certainly prevail *most* in persons who, from whatever cause, are weak and unhealthy; and particularly in scrofulous children. There are, however, many exceptions to this: they are not uncommon in individuals who are robust and vigorous. Intestinal worms, of all kinds, are more abundant in some situations than in others; especially in places that are low and moist. They are accordingly very frequent in Holland, and in some parts of Switzerland. Wherever there is much debility of the digestive organs—in leucophlegmatic habits—in persons who secrete habitually a large quantity of mucus—worms are apt to congregate. The children of the negroes in the West Indies are wonderfully infested by them.

It more concerns us to enquire into the general symptoms, through which the existence of worms in the alimentary canal may be ascertained, or suspected.

Those symptoms are very multifarious; and, for the most part, very equivocal. I know of none that can be reckoned certain or pathognomonic, except the actual appearance of one or more of the animals, or of portions of them, in the excrements of the body. Yet that they do give rise to a variety of morbid phenomena—which morbid phenomena are, however, liable to be pro-

duced by other causes also—there can be no question.

The most common of these are well known to all nurses and old women: such as colicky pains, and swelling of the belly; picking of the nose, in consequence of itching and irritation there; itching of the fundament; a foul breath; grinding of the teeth during sleep; a variable and capricious appetite, sometimes voracious and insatiable, sometimes none at all; and irregular bowels.

Worms sometimes give rise to strange, and even severe, *nervous* symptoms, explainable upon the principle of the reflex office of the spinal cord. We conclude that the symptoms are owing to worms in such cases, because they cease when the creatures are got rid of. Some examples of this I have already noticed. Thus Dr. Elliotson's infant patient lost a chronic cough upon the expulsion of the live larvæ of the common fly. Bremser gives a very similar case. A child of eleven, afflicted with tænia, had a troublesome dry cough. It was observed that the cough was suspended for two months, just after a very large portion of the worm had been brought away by anthelmintic medicines. This kind of coincidence happened, not once only, but three or four times; and at length, when the whole of the worm had come away, the cough was permanently cured. I mentioned, some time ago, the frequent association of intestinal worms with epilepsy, which is then of the eccentric form: and I stated that a certain nobleman voided some kind of worm (a tapeworm I think) from his bowels, and was thenceforward free from epileptic fits, under which he had long laboured. A curious circumstance, illustrating the fact that irritation of the mucous membrane of the alimentary tube may affect distant parts, is quoted by Dr. Joy from Albinus. A soldier received a wound, which led to the formation of an unnatural anus, in front of the abdomen, and in the track of the colon. Through this opening the mucous membrane of the bowel sometimes protruded; and whenever it was out, and exposed to the contact of cool air, the patient began to cough; and continued to do so till the mucous surface was warm again. Partial palsy, amaurosis, aphonia, and other nervous symptoms, occasionally depend upon the presence of worms in the intestines.

But let us examine into the symptoms which are more or less proper to particular species of intestinal entozoa; and into the treatment which they severally require.

A variety of symptoms are ascribed to the *ascaris lumbricoides*. Dr. Baillie says that the most characteristic are a tumid belly, emaciated extremities, offensive breath, and a deranged appetite. To these may be added colicky pains of the abdomen. When these animals get out of the small intestines, and

ascend into the stomach or œsophagus, they may occasion pain, nausea, vomiting, even convulsions. They have caused death, as I mentioned before, by crawling into the biliary ducts, and into the chink of the glottis. Sometimes, on the other hand, they emerge, unexpectedly, from persons who had received no previous notice of their presence.

This, the commonest parasitic tenant of the human bowels, is also a troublesome one to eject. A great variety of anthelmintics have been cried up as successful against it; but brisk purgatives, and bitter medicines in the intervals, have the best evidence in their favour. These animals seem not to like steel; and my own plan of assailing them is that of purging the patient from time to time by calomel and jalap, and administering, three times a day, some preparation of iron; the sulphate, or the muriated tincture. I believe that most of the patent worm medicines consist of mercury, jalap, and scammony, given in strong doses. The foetid drugs, assafoetida, galbanum, valerian, are often given. Cowhage also, the *dolichos pruriens*, which is supposed to tease the skin of the parasite no less than that of the human worm; and tin-filings, which are thought to bruise or lacerate the offenders, are favourite remedies with some persons. I have never tried them. The oil of turpentine I have not found so successful in expelling this species of *ascaris* as I shall presently show you that it is against the tape-worm. Croton oil has been much commended, either given by the mouth or rubbed upon the abdomen. Common salt, coloured by cochineal, and exhibited every morning in half-drachm doses, was found by Dr. Rush to be very successful.

The symptoms produced by the *ascaris vermicularis* are itching and irritation about the anus, especially in the evening, and aggravated by the warmth of the bed, and by whatever overheats the body. I would refer you to a paper by Dr. Heberden on this subject, in the first volume of the *Medical Transactions*. The case he describes is the more valuable, as it was related to him by a *physician* who was all his life plagued by these thread-worms. Generally, however, they infest children; and become fewer, and at length disappear, as childhood passes into youth. When they do accompany life through its several stages, although they are a source of serious annoyance and suffering, they do not appear to shorten the duration of the patient's existence.

To introduce at one end of a tube, several yards long, substances which are intended to act upon animals that live quite at its other end, would be a very round-about course. Whether a purgative effect, or a specific destructive effect, be the object, enemata are

preferable to medicines given by the mouth. *Bitters* offend and destroy these little worms. I have relieved many patients from their tormentors by prescribing simply the infusion of quassia as an injection. Tobacco clysters are praised; but the remedy is a hazardous one. Dr. Darwall says of an enema composed of half an ounce of the muriated tincture of iron mixed with half a pint of water, "there are few cases so obstinate that this will not suffice to overcome." Lime water, injected into the rectum, forms another effectual remedy for *ascarides*, and (as pharmacologists love to speak) a rather *elegant* one.

Thread-worms may be scooped out of the rectum, with the finger. Old women fish for them with a piece of fat meat, or a candle, wherewith the entangled worms are drawn out of the bowel. Perhaps, in troublesome cases, the plan laid down by Martinet is as good as any. He recommends three successive injections: the first merely purgative; the second specific (common salt in solution, cold vinegar and water, lime water, some bitter infusion); the third, oleaginous and soothing. Oil often allays the itching. This teasing symptom may sometimes be quieted by applying a towel wetted with cold water, to the fundament, while in bed.

With some means of this kind for expelling the worms, appropriate measures should be combined for improving the general health.

I know of no signs by which the presence of the *tricocephalus dispar* is revealed; and I am equally ignorant of any remedies for it.

That a *tape-worm* is within, we know when joints of it are voided. Numberless symptoms have been ascribed to this huge internal parasite. The following are probably the most distinctive. Uneasy feelings in the epigastrium, which often abate or are removed by eating; the appetite generally craving, but sometimes bad; itching of the nose and of the anus; nausea; colic; giddiness; a sour breath. Less frequently loud borborigmi occur; and sometimes convulsions.

Louis has watched and recorded, with his accustomed minuteness, the symptoms of ten cases, in the wards of La Charité. Seven of the patients were males, and three females. The youngest was a boy of 12, the son of another of the patients; the oldest was 74. Most of them were in comfortable circumstances, and had been habitually well fed. The greater number of them had for some time been passing fragments of tape-worm, with their stools, in their clothes, and in their beds. In one of the cases the articulations had been twice only detected in the stools, and each time upon the operation of a purgative.

In all the patients but two, the other symptoms commenced when the evacuation of the fragments commenced. This renders it probable that the worms begin to give annoyance when they get into the large intestine. The temporary relief that results from the expulsion of portions of the animal strengthens that supposition. The case is mentioned in the *Medico-Chirurgical Journal* of a man who was in the habit of freeing himself of large fragments of tapeworm by introducing a stick into the rectum, and twisting the worm round it till it broke.

The chief symptoms observed in Louis's cases were colicky pains of the abdomen; itching of the anus, and of the end of the nose; uneasiness of the epigastrium; and deranged digestion and appetite.

Pain in the abdomen occurred in *all* the instances: but it differed in different cases, both in degree and in kind. It was intermittent; and mostly felt towards the flanks.

There was itching at the margin of the anus in seven of the ten cases; itching of the nose in four. With one exception only, itching was present in one or the other, or in both of these situations.

The appetite was craving in one patient; unaffected in four; variable or bad in all the rest. In all, slight emaciation was observed. In all, the pupil of the eye was of its natural dimensions. This is noticed, because dilatation of the pupil has been set down as one of the symptoms of *tænia*.

Louis thinks that the following combination of symptoms indicates with tolerable certainty the presence of some kind of worm in the intestines. Pain in the belly; colic of various degrees of intensity, unaccompanied by diarrhoea; itching about the anus, and at the end of the nose. If pains in the limbs, lassitude, and nervous symptoms exist also, the diagnosis is strengthened.

We have a very effectual remedy for *tænia*—at any rate for the tapeworm of this country—in oil of turpentine, given in large doses. The anthelmintic virtues of this substance were not generally known till a paper on the subject, by Dr. Fenwick, of Durham, was published, in 1811, in the *Medico-Chirurgical Transactions*. A sailor, plagued by this parasite, had noticed that large fragments of the worm were passed whenever he had swallowed an unusual quantity of raw gin. Thinking that a stronger spirit might have a stronger effect upon his internal enemy, he tried a glass of turpentine, which completely cured him. This practice was then taken up by some unprofessional persons, who gave turpentine, with similar success, in several cases. At last Dr. Fenwick, in conjunction I believe with my friend Dr. Southey, investigated the subject; and when they had satisfied themselves of the value of the remedy, the

result of their enquiries was communicated by Dr. Fenwick to the late Dr. Baillie, in a letter which was read before the Medical and Chirurgical Society. But there is nothing new under the sun. Fifty years ago, Mr. Malden, in the *Memoirs of the London Medical Society*, recommended the same remedy, in the same doses, for the same purpose. But his recommendation had been neglected, or forgotten.

The dose of turpentine is from half an ounce to two ounces. It may be given in combination with castor oil; or castor oil may be administered afterwards to assist its purgative effect. It should be taken in the morning, fasting: and no drink should be admitted into the stomach until the medicine begins to operate, lest sickness and vomiting should be provoked. The worm generally is voided, dead, within an hour or two.

The inconveniences of turpentine as a remedy are its nasty taste, the sort of intoxication it is apt to produce, the distressing sickness it excites in some persons, and the strangury it sometimes occasions. This effect of it, however, is less common from a large than from small doses of the oil. The bowels should be kept open with castor oil, so long as the urine retains the violet smell, which indicates the presence of the turpentine in the circulation.

Upon the continent a celebrated empyreumatic oil, called Chabert's, is in great repute. It contains turpentine; but is still more nauseous than it. One part of the empyreumatic oil of hartshorn is mixed with three parts of oil of turpentine. After the mixture has stood for three days, three-fourths of it are to be distilled over, in glass vessels, by means of a sand bath. Chabert was a veterinary surgeon; and had used this remedy with remarkable success upon domestic animals, cows, dogs, and sheep. Bremser, after testing its safety by taking it himself, administered it, he tells us, to no less than 500 individuals troubled with *tænia*. Among these were two children, a year and a half old. He found it both a powerful and a permanent cure. Of the whole number treated there were but four who required a second course of the remedy. It seems to kill both the worms and their ova. The dose is two teaspoonfuls, night and morning, until four or six ounces have been taken; a purgative being from time to time interposed. If that dose produces any confusion of head, it must be diminished.

Bremser admits that this curative process is tedious, but affirms that, on the other hand, it is safe, and but little inconvenient. When the patient has continued free from any symptoms of tape-worm for three months, he concludes that the cure is absolute. Other practitioners agree with him in attesting the efficacy of this oil; but are not

so confident about its perfect safety and convenience.

Another great remedy is the bark of the pomegranate-root. This is at least as old as the time of Celsus. It has long been employed in India. Its value has only been recently appreciated in France; and in this country it is not much used, I believe, even yet. You may read a very instructive account of its effects in a paper communicated to the Medical and Chirurgical Society by Mr. Breton. He boiled two ounces of the fresh bark of the root in a pint and a half of water, till the decoction was reduced to three quarters of a pint. Two ounces of this, cold, he gave to a patient who had tape-worm, and repeated the dose every half hour until four doses had been swallowed. About an hour after the last dose, an entire *tænia* was voided, alive.

The bark dried in the sun he found still more active. A stout man, 40 years old, took a decoction prepared in the same way as the former, only with the dried instead of the fresh bark. Three hours after the first dose, a live tape-worm came away, 19 feet two inches long. The medicine thus prepared seemed to be too strong; the patient was sick, giddy, and trembling for several hours. He, also, had taken four doses.

To two boys, of seven and ten years of age, he began early in the morning to administer one ounce of a decoction made of half the previous strength, every half hour, for six times; and then stopped. In the middle of the day he resumed the medicine in half-ounce doses. Giddiness and faintness soon came on; and, about five o'clock, each of the patients passed a *tænia* of the *solium* kind.

A scruple of the powder was given, mixed with water, every hour, for five successive hours, to a boy of nine. Forty minutes after the last dose a living *tænia* was expelled.

The same quantity was given to a girl, ten years of age; beginning at eight, and repeating the dose hourly till twelve o'clock. At twenty-four minutes past one she voided a living *tænia lata*: and the next morning, at nine o'clock, a dead *tænia solium*. This curious case shews that the two species may exist in the same person at the same time.

Mr. Breton relates other examples; but those which I have cited are quite sufficient to demonstrate the power of this substance. The bark appears to act upon the worm as a poison. In tepid water *tæniæ* will live for several hours. When they are plunged into the aforesaid decoction, they writhe and manifest great uneasiness. Between the first dose of the medicine and the expulsion of the worm the shortest period appears to have been three hours, the longest twenty-five.

Louis' ten cases, before referred to, were

all treated by a nostrum called the potion of M. Darbon. It proved successful in all. Eight or ten ounces of it were taken in the morning, before breakfast; and the cure was accomplished by that single dose. It is said to be quite safe, to have no very decided taste, and to cause no farther inconvenience than a slight colicky feeling, and uneasiness in the epigastrium, less than is produced by many a purgative: and even these sensations were probably owing to the movements of the worm; for when, after the lapse of four months, the dose was repeated, it was followed by no inconvenience at all. The medicine is not strongly cathartic, and sometimes requires the aid of a lavement. In each of these cases the expelled *tæniæ* were apparently dead. Their *heads* were detected in the evacuations: in one instance seven heads were seen. Louis says that within a few days at farthest after the discharge of the worms, all the previous symptoms of their presence ceased; and the patients improved in respect to appetite, digestion, complexion, flesh, and strength. They all remained well four months afterwards, and then the potion was again administered; but it brought away no more worms. Some of the patients, who had previously tried other modes of cure, had never enjoyed so long an interval of freedom.

Various other remedies have been employed, and employed with more or less success. One of them, the root of the male fern, formed the basis of a nostrum, called Madame Nouffer's, which was so highly thought of, that in 1776 the King of France gave that lady some hundred pounds sterling for the secret of its composition. I think, however, you will find the oil of turpentine equal to the cure of tape-worm in most instances. Should it fail, or should circumstances forbid its use, I would advise you to resort to the bark of the pomegranate root. It seems probable that M. Darbon's remedy, if its nature were divulged, would supersede all others.

#### ON

#### FRACTURE OF THE SKULL\*.

BY R. A. STAFFORD,

Surgeon Extraordinary to His Royal Highness the Duke of Cambridge; Senior Surgeon to the St. Marylebone Infirmary.

FRACTURE of the skull is caused much in the same manner as concussion—by a severe blow upon the head, but so much more violent that the cranium is broken; consequently, that, independent of the fracture, the worst symptoms also of concussion occur.

\* Being the substance of a lecture delivered at the St. Marylebone Infirmary.

Fracture of the skull may be divided into three classes: 1st, simple fracture; 2nd, comminuted fracture; 3d, fracture with depression on the brain.

Simple fracture is a mere split of the bone; comminuted, the bone being splintered at more than one division, something like, perhaps, a pane of glass being struck with a small stone, and not going through it, being radiated from the centre. Fracture with depression is where the bone is beat in upon the brain. The first two of these are not much more than concussion: the bone is not displaced; consequently union will take place without trouble. But fracture with depression is indeed a serious injury—an injury difficult to treat; full of doubt and danger.

By way of simplifying the matter, I shall divide these fractures into simple and compound. Simple fracture with depression, is, where only one piece of bone is broken and depressed to a lesser or greater extent, resembling a wedge. Compound fracture is, where the bone is broken into several pieces, and then thrust in upon the brain. I have seen several cases of simple fracture of the skull with depression; and these are those which cause so much discussion, whether you should trephine, or whether you should not trephine? It is laid down in books, and I believe more particularly by Mr. Abernethy, that if there is depression with symptoms of compression on the brain, you ought to trephine; and, on the contrary, if there is depression without those symptoms, you ought not. Now in the first opinion I perfectly agree. You must trephine—trephine by all means: in the second I am doubtful. In my opinion, it depends upon the *depth* the bone is driven in. If the bone is only depressed just below the outer surface of the external table, then there will be no necessity to trephine, or even to the diploe, between the inner and outer table; you need not do it. But if it is driven lower than that, I certainly should do it, or use the elevator, if possible, to raise up the depressed portion. My reason is the following: when the bone protrudes deeper, its edge rests upon the dura mater, and presses upon the brain; consequently, although there are no symptoms *then* of compression, the fractured edge becomes a foreign body, and produces inflammation and its consequences, suppuration, &c., and most probably death. I have seen such cases. I remember a case where a woman received a blow on her head, and her skull was fractured. The injury took place on the right parietal bone. A single portion of the skull was depressed, about the fourth of an inch. She had no symptoms of compression, and the case was discussed by men of the greatest talent. It was decided not to trephine. In a few hours

inflammation came on, she was delirious, and she died. On examining her head, the edge of the bone was found resting upon the dura mater, and pressing upon the brain. Inflammation had taken place, and pus had formed. Other cases of the kind have occurred to my knowledge, and they made a great impression on my mind. I therefore came to this decision; that if the fractured portion was beat in so as to become a foreign body resting upon the brain, I should trephine, or use the elevator, if possible, to raise it up, whether there were symptoms of compression or not.

In the days of Mr. Pott, a most distinguished surgeon of his time, and who wrote upon injuries of the head, it was the fashion to trephine whether the bone was depressed or not. Mr. Abernethy first drew the distinction when the operation ought to be performed, and when not: that is to say, it ought not to be done when there are no symptoms of compression. The rules laid down by Mr. Abernethy are excellent; but I think the description of cases I have mentioned are exceptions to them. I am aware that cases are mentioned where the depressed piece of bone has been driven very deep upon the brain; so deep that in one instance the indenture resembled a funnel, and yet the patients have recovered. This no doubt is true, but the cases that have not recovered, under the same circumstances, are not related. I am inclined to think that if a record of all the cases of this description were kept, it would be found that the recoveries would be fewer than the deaths. It appears to me, that if symptoms of compression come on some time after the accident, it is usually too late to trephine, as the broken fragments of bone have already acted as a foreign body on the brain, and the mischief resulting from an extraneous substance resting on so delicate a texture has produced the natural consequences—inflammation, softening, and the formation of pus.

And now I shall speak of what I term compound fracture of the skull. I mean when the bone is broken in more pieces than one, and driven deep upon the brain. Such accidents happen from the head being hit at a particular point. For instance, the head may be struck by a hammer, the corner of a stone-step, or any thing hard, such as a piece of iron projecting from a wall, &c. The best thing I can illustrate this accident by is, the breaking of the shell of one egg when another has been pressed against it. The fractured egg is broken into several different parts, and is at the spot pressed in upon its contents, the centre being the deepest.

It generally happens in this description of fracture that the bone is not only depressed, but that there are the most confirmed symptoms of compression of the brain,

and that you cannot hesitate what to do. You have nothing else left but to trephine. But I have seen two cases of this kind where there were no symptoms whatever of compression; and these are the cases which so confirmed me in the necessity of trephining, when the fractured bone became a foreign body resting on the brain, when there were no symptoms of compression. During the time I was house-surgeon to St. Bartholomew's Hospital, I was called up early one morning to see an Irishman who had been fighting with his fellow, and had received a blow upon his head. I examined the wound, and found the skull was fractured, and the broken pieces of bone were driven at least half or three quarters of an inch upon the brain. I was surprised to find that the man had no symptoms of compression. He walked about the ward, and talked as if he had only received a slight wound on the head. He told me all about the quarrel and the whole proceeding, as if but little had happened. It being laid down as a rule that if there were no symptoms of compression in fracture of the skull, you ought not to trephine, I dressed the wound, and sent for my superior officer. He came, and I told him the nature of the wound—that there was fracture, with depression of considerable depth. He did not believe me: he quite laughed. The man was as rational as any patient in the ward, and could answer any question you chose to put to him. I requested him to examine the wound. He answered, "No, you have dressed it very well; and if there were depression, it is not the practice to trephine until symptoms demand it." I began to think I was wrong, and had made a mistake. However, on the same night the man became comatose, insensible; his breathing stertorous: in fact he had exactly the same symptoms as in apoplexy. I sent again instantly to the surgeon whose patient he was. He came, and saw the state the man was in. He examined the wound, and found he had depression. He said to me, "You are right; I shall immediately trephine this man. I was not justified in doing this operation before: no symptom existing to demand it." The man was trephined: the brain at the part was inflamed and softened, and pus had formed. He died.

Since this case I have met with another of a similar description, not under my own care, and which occurred very much under the same circumstances—a quarrel and a blow on the head. This man was sensible for two or three days; he became comatose, with apoplectic symptoms, and died. In such cases as these I am inclined to think it would be better to trephine as soon as possible after the receipt of the injury. By doing this the depressed portion of bone will

be prevented from becoming a foreign body. It appears to me, that the rule laid down, that "you should never trephine when there are no symptoms of compression," is too stringent; it should depend upon the *depth* the bone is driven in upon the brain, and whether the fractured portion will become a foreign body or not, resting on or being driven into its substance.

There is one thing we should be very careful of when we have trephined, which is, to examine well that we have not left a splinter of bone behind. A splinter of bone left in the brain will cause inflammation, suppuration, and death. I have known one or two cases where this has occurred, and the patients died.

There is another description of fracture which I have not mentioned, which is, that of the basis of the cranium. To produce this accident great force is required; and it generally is caused from falling from a great height upon the top of the head, whereby a *contre coup* is given to the base of the skull, by which it is broken. It can be known by the severity of the concussion, and frequently blood issues from the ears and nose. Should there be compression from extravasated blood, there is but little hope of the patient. We must treat fracture of the base of the skull as we would concussion; but it is a most dangerous accident, and the patient more often dies than lives. I have seen many of these cases, and shall relate one. A man fell from a scaffold upon the top of his head. He was taken up senseless, and he had bleeding both from the nose and ears; but there were no symptoms of compression of the brain. He was treated actively for the concussion, but his senses never returned; and within three days he died. On examination of the skull, the basis was fractured completely across, from one meatus auditorius to the other. The whole substance of the brain, on being cut into, presented the bleeding points of enlarged vessels; and the membranes were inflamed.

There are other cases of fracture of the skull. Sir Astley Cooper mentions a case of circular fracture, "commencing at the top of the head, passing down on each side, through the temporal bone, and meeting at the basis." There are fractures of all descriptions. Indeed, when we consider the peculiarity of the accidents which occur to the head, it would be perfectly ridiculous to attempt to describe all of them: in fact, it would be impossible.

The notes of the following cases, which occurred in this infirmary, were given to me by Dr. Boyd.

#### *Fracture of the skull.*

Robert Davis, a lad, in sliding down

some banisters overbalanced himself, and fell on his head on some flags, the height of 25 feet. He was taken up in a comatose state. There was a slight scratch on the crown of his head, and a considerable effusion of blood beneath the scalp; the respirations, as well as the pulse, were slower than natural; the action of the heart became irregular, and the breathing slower till it stopped. Death occurred within two hours after the accident.

*Examination 28 hours after death.*—About four ounces of fluid blood extravasated beneath the scalp. A fissure in the skull about seven inches in length; it extended from the right orbit to the coronal suture. The orbital plate was also divided. A quantity of blood effused around the eyeball, and a thin layer also over the hemispheres of the brain, beneath the arachnoid membrane. The cerebral substance itself not injured.

*Fracture of the left malar bone, extending inwards around the roof of the left orbit; a small wound of the skin, corresponding to the outer edge of the left eye-brow.*

William Chapman was brought by two drunken men to the infirmary, who said that they had picked him up in the street, but knew nothing further of him. The man was unable to give any account of himself at the time he was admitted. The person for whom he worked stated subsequently that he had been bottling ale, of which he had drank sufficient to make himself tipsy. He went out of the cellar to make water, and fell off a step about six inches high on his face, which occasioned the wound; it bled at the time, and was dressed. The man walked home that evening, about a mile. He returned to his work on the following day, but did not feel equal to it. This occurred on Wednesday; he did not come to the infirmary for two days after. He was treated by losing blood locally from the head, by the constant application of an evaporating lotion, purging frequently, and taking calomel and opium combined. He died five days after admission, with typhoid symptoms.

*Examination 36 hours after death.*—There was softening of the anterior part of left hemisphere, which rested on the orbital plate, but no displacement of bone. The lateral ventricles contained some purulent matter. There was considerable effusion of lymph around the medulla oblongata and cerebellum. As I have remarked before in a former paper, there have been two cases of fracture of the skull this year under my care in this infirmary: they were both simple fractures, without depression. They were treated like concussion of the brain, and did well.

And now I have been talking of compression of the brain, but I have not described

the symptoms. The symptoms of compression of the brain are total insensibility, a dilated pupil, stertorous breathing, a slow and perhaps irregular pulse, a lifelessness of the whole body. If we take up the arm, it falls down again; and if we lift up the hands, the head lolls on the shoulder. In short, the patient has exactly the same symptoms as in apoplexy. We know the cause—there is compression on the brain from fracture, or from extravasated blood.

It sometimes happens that a blow upon the head causes the rupture of a blood-vessel on the brain, when symptoms of compression take place. Under such circumstances we must trephine immediately at the point the wound takes place, and remove the coagulum. The following is a case of the kind, which occurred while I was at St. Bartholomew's Hospital:—A man fell down Waterloo Bridge steps, and struck his head. He was taken up senseless, and carried to the hospital. His head was examined, but there was no fracture, and only a contused wound on the right temple. The pupil of the eye was dilated; the pulse labouring and slow, about 50; the breathing stertorous; and the whole body cold, and in a lifeless condition. Instead of getting better he got worse. He was trephined, and a large coagulum of blood was found. It was removed, but it formed again. The vessel could not be found. The man died in a few hours.

It has often occurred to me that the instruments for trephining might be improved. To bore a large hole in a man's skull, to raise up depressed portions of bone, when it may be done in a much simpler way, appears to me absurd. I believe there are many cases where it might be avoided; for instance, in simple fracture with depression, when only one piece of bone is driven in upon the brain, like a wedge, and it cannot be lifted up by the common elevator, why not use a file of a particular construction, and file a groove in the centre of the whole bone exactly opposite to it? By this manoeuvre an instrument or elevator adapted to the groove, and made exactly to fit it, might be introduced under the depressed portion, by which it could be raised up.

In complicated fractures, where more pieces of bone than one are depressed, a groove, corresponding to each depressed portion, might be filed on the edge of the unbroken bone, and thus each fractured portion might in the same manner be raised or removed. By employing such means as that the operation for these, it is my opinion trephining would be seldom required. I have invented some instruments for the purpose, which can be seen at Mr. Ferguson's, surgeon's instrument maker, Giltspur Street, St. Bartholomew's Hospital.

And now I have to speak of the treatment.

We must remember that fracture of the skull is a double injury—the mechanical injury and concussion of the brain. If there is depression, we will relieve the mechanical injury by trephining, or using the elevator; but we must not do this alone; we must treat the patient for concussion of the brain likewise. I have already stated how to treat concussion of the brain. We must bleed freely, both generally and locally. The patient must be kept on the lowest diet. A cold lotion must be constantly applied on the head. The bowels must be kept open, and fever kept down. If the symptoms run on, we may give calomel and opium to affect the mouth, the principle of which I have pointed out to you. It is also of great consequence that we should dress the external wound with great care, bringing the cut edges together, so that they may heal by the first intention: being also careful that the plaster is so applied that no air can get to it. It is a good plan to dissolve sealing-wax in spirits of wine, and brush over the plaster this solution. It will become dry, and will prevent both the air and the wet applications from getting to the wound.

In conclusion let me advise you to take notes of these cases. They are too often connected with manslaughter and murder. You are in a very responsible situation. A judicial inquiry most probably will be made, and you are a witness of the greatest consequence.

#### REMOVAL OF UPPER JAW.

By JAMES DOUGLAS, A.M.

Lecturer on Anatomy at the Portland Street Medical School, Glasgow.

(For the London Medical Gazette.)

IN the MEDICAL GAZETTE of the 29th October, 1841, I related the case of Adam Tennent, æt. 19, from whom I had removed, a year before, the whole upper jaw-bone, with the exception of its tuberosity, for a tumor of a medullary character, growing from the lower part of the bone, and distending the maxillary sinus. He still remains quite well, nineteen months after the operation. But as it is unfair to relate only successful cases, and conceal those which terminate unfavourably (although this is too commonly the practice), I proceed to give an account of another similar case, where the disease had gone much further, requiring the removal of the whole maxilla of one side, and about a third of the other; and where the pa-

tient recovered from the operation, but died four months afterwards, from the recurrence and extension of the disease.

Mrs. M'Kenny, æt. 35, October 3d, 1841.—About seven months ago observed gums of upper jaw to swell, attended with superficial ulceration. About four months ago had all the five double teeth extracted from right side of upper jaw. About two months ago right cheek began to swell, and became much more prominent than the other. She showed her mouth to several surgeons, one of whom gave her mercury, which did her a deal of harm, and others prescribed washes and various remedies, which did her no good. She was brought to me two days ago, when finding the incisors and canine teeth of the upper jaws loose, I extracted them, and found the soft matter forming the tumor adhering to them; it having taken the place of their sockets, which had become absorbed or converted into it.

A tumor having the characters of malignant *epulis* is seen growing all round alveolar process of right upper jaw, and round left as far as canine tooth. It has the form of red granulations, soft, yet pretty firm, and seemingly covered by the mucous membrane. Palate has a disorganized look, and there is a hole into nose about halfway back, in the middle line, which would admit a quill. No very accurate examination can, however, be made of the inside of the mouth; for a small abscess has formed in right cheek, just below the malar eminence, causing swelling and redness, from which pus can be squeezed into the mouth, by the side of the gums; and this prevents the mouth from being opened. There does not, however, seem to be anything malignant in this abscess or swelling; it would seem to be merely the result of the irritation produced by the state of the gums. She complains of little pain in tumor, but describes a darting pain as passing occasionally towards right temple. Probably this also depends on the abscess.

She is emaciated, and looks much worn out; pulse 100; respiration 24; no pectoral symptoms; sleeps tolerably; bowels free. Has had several children; the last two years ago. Catamenia suppressed for last two periods.

I recommended an operation for the removal of the tumor, with the bones.

October 4th.—I took Dr. Macfarlane (one of our most skilful operating surgeons) to see her, who fully concurred in the necessity for an operation, although satisfied that the chance of success was not very great. She immediately gave her consent.

5th.—At noon I proceeded to the operation, assisted by Dr. A. D. Anderson, Dr. J. G. Fleming, and Mr. Lyon; Dr. Macfarlane being prevented, by a call just before the hour, from being present. The patient was placed in a chair facing a window, her head supported by Dr. Fleming against his breast, and her hands held by her husband, who knelt behind.

Standing in front, I made an incision from just below inner canthus of right eye, in the hollow by the side of the nose, round the ala, and down the right edge of the filtrum, through the upper lip. The flap having been dissected up as far as it could be, I made another incision from the malar eminence through the abscess, obliquely downward and forward to the angle of the mouth, passing above the orifice of the parotid duct. The flap was then dissected back as far as the junction of the malar and maxillary bones, and the latter was found so soft as to yield to the knife. The posterior border of the bone was nearly brought into view, some part of the masseter being divided. The contents of the orbit were now raised from that part of its border formed by the maxillary bone, the scalpel being pushed back along its orbital plate; the left side of the upper lip was separated from the bone, and the nose, with its cartilages, was loosened from the anterior nasal spine. A strong pair of Liston's forceps were now used: one blade being introduced into the left nostril, the palate plate of the jaw was divided. The vomer was next divided in the same way; then the nasal process, on a level with the lower edge of the pons plana of the æthmoid bone; and lastly, the union of the malar and maxillary bones. Care was taken here to cut into the sound bone. The maxilla was now nearly loose; a few touches with strong scissors at the back part brought it away, by depressing it into the mouth, and the right palate bone came away along with it. The soft palate was now divided, and the mass removed. On examining the

removed bone, a small portion was discovered to have been left far back, but was easily dissected out. The bleeding was very trifling; indeed the only vessel which threw out blood so as to require ligature, was the facial, divided in the second incision.

It now only remained to remove the diseased portion of the left maxilla. The lip was dissected up as far as the second bicuspid, and the alveolar process was nipped through with one stroke of the forceps, breaking out that tooth, and the body of the bone was cut across with a second, below the lowest spongy bone. The jaw seemed hard and sound when cut. The mouth having been well sponged, the actual cautery was freely applied. The whole, including the examination of the pieces removed, occupied about twenty minutes.

Oiled lint was now stuffed into the cavity, and the two incisions were closed with four points of twisted, and six of interrupted suture. Strips of court-plaster were interposed between these. The face looked wonderfully natural. She was very cold, although she had had some hot spirits and water before the dressing. A bandage was passed round the head and face so as to give support. Pupils were observed to be dilated to the utmost (was this an effect of the pain in general, or of the cautery on the second trunk of the fifth nerve, or on the inferior oblique branch of the third?). Forty drops of laudanum were given in a little spirits and water from the spout of a tea-pot, and swallowed without much difficulty. In the evening she was tolerably easy, and took some thin gruel, and forty more drops of laudanum.

*Examination of parts removed.*—Right maxilla is found almost entirely converted into a semi-transparent firm substance, somewhat gristly, except orbital plate, which is quite healthy. Body of palate bone, and inferior spongy, have undergone the same change; in the latter there is not an osseous particle remaining. Infra-orbital nerve has been divided just behind where it goes to sink into its canal, just behind where the bone broke in removing it. Palate presents two projections; one into nose, the other into antrum. Its firm rugæ, covered with mucous membrane, are still entire, though the bony

arch has become quite soft. The antrum was filled with a soft brainy mass. The portion of the left maxilla which was removed in the second stage of the operation seems to have been divided through firm healthy bone; so that we may hope that all the disease has been really got away.

6th.—Slept a considerable part of the night; complains little of pain; asked for her porridge in the morning, and took it mixed thin with milk. Pulse only 90.

7th.—Had a pretty good night. Skin hotter, and pulse up to 100. Eyelids œdematous. Took off the bandage and lint, and found face scarcely at all swelled; whereas my former case swelled very much. Union is taking place along both incisions. Removed one needle, and put a strip of court-plaster in its place.

8th.—Removed the other three needles, and the stuffing of lint. Pulse only 80; requires physic. To have a little castor oil, and some beef-tea.

9th.—Removed all the stitches. Union now complete; swallows wonderfully well. Dipped the lint with which the cavity is stuffed in camphorated oil to lessen the foetor, and stimulate gently.

11th.—Took all the plaster off. Line of union perfect. Washed out the cavity with a syringe. To have some porter.

26th.—Three weeks complete. Cavity is filling up; sleeps without laudanum; dresses it herself; gains strength slowly. I have supplied her with some porter, and given her some tincture of steel.

November 2d.—A month to-day. Has been using an injection of zinc, under which the cavity from which the right maxilla was removed has granulated and contracted very much. I am very sorry, however, to see a portion of fungous growth beginning to sprout from left maxilla, close to its alveolar border. General health much improved. Two glands are felt enlarged behind right ascending ramus of lower jaw, immoveable, and painful on pressure. To rub them with oil.

6th.—The fungous growth is now quite decided. A very suspicious thickening of septum nasi is also seen, of a dark red colour superficially, and ulcerated in each nostril. The space from which the right jaw was removed still

granulates well. The glands behind the lower jaw are no longer enlarged. Complains much of deep-seated pain in right side of head.

18th.—To-day, observing right eye slightly protruded and vacant-looking, I inquired if she saw with it; and was surprised to find it quite insensible to the candle, a few inches off; pupil being moderately dilated, and quite immoveable. Pain in the head has increased, and she has been mostly in bed for three days. I showed her to Dr. Macfarlane immediately after I observed the fungus appearing on left side, and he said he thought it would be a pity to let her die without trying to remove it, as the wound on the other side was looking so well. But now I am persuaded that there is disease going on deeper in the right side, in which the optic nerve has become implicated (for she saw me with the right eye weeks after the operation), so that any further attempt to remove the disease by operation would be worse than useless. I must therefore abandon her to her fate.

Dec. 28th.—The disease is steadily progressing. Right eye is still more protruding, and has been for a month quite insensible to light. Its eyelids much swollen, and of a dusky red. Left eye almost quite insensible also. Has been for three weeks entirely confined to bed.

Died February 4th, 1842, four months exactly after the operation, quite exhausted. Her sisters would not permit any inspection of the body.

I may mention a curious case which I saw some time ago, of spontaneous separation of the upper jaw. A boy had cancrum oris, which took on a healthy action, and healed. The upper jaw, however, died, and came away entire, with the exception of its nasal process. It has separated at the sutures from the palate bone, the vomer, the malar, and the maxilla of the opposite side. The bone is not completely developed; the two bicuspidæ, and the dens sapientiæ, being still deep within the jaw. The surgeon whose case it was promised to give me a particular account of it; but I have never been able to obtain it from him.

---

## FUNGUS OF ANTRUM—REMOVAL OF SUPERIOR MAXILLA.

By W. LYON,

One of the Surgeons to the Glasgow Royal Infirmary; and Lecturer on Surgery in the Portland Street School of Medicine.

(For the Medical Gazette.)

JEAN SCOTT, ætat. 45, Feb. 12th, 1842. Three months since began to complain of acute lancinating pains, shooting from right cheek over same side of forehead, and becoming very severe at night; some swelling appeared over right maxilla at same time, which has since remained stationary. In addition to swelling above described, the right eye is pushed upwards, and projects considerably; while it feels tense and is less moveable than the other. Some fulness in right temporal fossa, which feels doughy, and is painful when pressed. Pressure upon palate, or upon the maxilla from inside of cheek, occasions pain, but no softness or yielding of the bone is perceptible. In right nostril, a tumor of irregular figure, and about the size of a turkey bean, is observed, which patient states was much larger until a few days ago, when a considerable portion of it was removed by the dispensary-surgeon, a copious discharge of blood following. General health good; catamenia have ceased; appearance healthy; patient at work until admitted.

A few days after admission she lost about half a pound of blood from right nostril; and in two or three days again, about a similar quantity from left. At both times bleeding was arrested by filling nostrils with lint, moistened in Sol. Sulph. Cupri.

15th.—To-day a consultation of the medical and surgical attendants of the hospital was held upon the case. Several of the consultants dissuaded from any interference, as they were of opinion the affection was malignant disease of the antrum, and was so extensively and intimately connected, that its eradication was impracticable, and therefore, though operated on, would return.

Again, other members of the consultation expressed their belief of the benign nature of the disease; that, whether benign or malignant, the antero-lateral parietes of the antrum should be opened, when the nature and connections of the disease would be made apparent: if it

was confined to the antrum, they recommended it should be cleared out, while, if the body of the maxilla was implicated, that the bone should be removed.

A third section of the consultants, of which I was one, insisted that, whether the morbid growth was malignant or benign, the bleeding from the nostrils, the prominence of the eye, the swelling in the temporal fossa, unequivocally shewed it to occupy each of those localities; if it had generally destroyed the parietes of the antrum, and incorporated itself with the adjoining parts, entire removal was impossible; that there was not positive proof of such condition existing, it being conceivable that the walls of the antrum were only expanded, not destroyed, and at any rate, we being in ignorance on this point, removal of the entire superior maxilla afforded the most rational procedure for effecting eradication of the morbid mass; while the previous opening of the antrum would be at least useless, and would render the operation more difficult and painful.

It was latterly carried that the antrum should be the first place opened, and ulterior proceedings determined by circumstances.

20th.—The patient being seated on a chair, and properly secured, a scalpel was pushed from the inside through the cheek, at a point corresponding to junction of malar bone with superior maxilla, and carried down until it cut itself out at the angle of the mouth. The thinned antero-lateral aspect of the antrum was easily opened with the gauge, when the cavity and the body of the bone were found filled with soft cerebral-like matter: it was now agreed the bone should be removed, which I proceeded to do in the manner advised by Mr. Liston, in his very useful work on Practical Surgery.

The right middle incisor being extracted, I carried an incision from the inner canthus down by the side and ala of the nose, detaching the connections of the latter from the edge of the maxilla, and cutting out in the mesial line of the lip. The coronary, and other branches of the facial, were commanded by the assistants; the flap dissected up until I reached the inferior edge of the orbit; the eye separated from the orbital plate of the maxilla, supported by a bent copper spatula, and the infra-

orbital nerve was then divided in its course along the floor of the orbit.

I now introduced the blades of a very strong cutting forceps under the point of junction of the malar with the maxillary bone, the edges of the blades being applied to the anterior and posterior surfaces of the bone, that division might be more easily accomplished than if the blades had been placed at the upper and under edges\*.

Entering the one blade of the same forceps into the upper part of the opened nose, and the other into the internal angle of the exposed orbit, the nasal process of the maxillary was easily divided, as was the alveolar ridge and bony palate, by placing one blade in the mouth, and the other in the floor of the nostril. I believe previous division of the alveolar ridge by the saw tends to prevent disagreeable splintering.

The bone was now easily depressed, its posterior connections broken, and lacerated rather than cut, in order to avoid bleeding; the soft palate cut across a short distance in front of the velum, and the bone entirely separated.

The hæmorrhage was copious, but not alarming; no vessels could be particularized; and, partly to repress the bleeding, partly to destroy the morbid growth and its sources, if not all removed, the red-hot iron was freely carried over the exposed surfaces of the sphenoid and ethmoid bones, from which the maxilla had been wrenched, and likewise into other parts of the broad, deep, and bleeding cavity. The wound was dressed in the usual manner. The operation was easy of execution, did not occupy much time, and the patient was only slightly and briefly exhausted by it. The cells and antrum of the extirpated maxilla were found filled with a soft brain-like matter.

21st.—Patient slept a short while last night: pulse now 72; right eyelid and side of face red and swollen; pain in throat during deglutition.

Hab. Ol. Ricini, ʒj.; Tr. Opii gtt. lx. h. s.

\* With the strongest forceps I have seen, I have found myself unable on the dead subject to divide the process formed at the junction of the malar with the maxillary bone, the thickness of the bone causing the handles of the instrument to be widely separated, so that they are only held by the tips of the fingers, and much power cannot be applied. I would advise intending operators to provide themselves with a more efficient instrument than is usually employed in this operation.

22d.—Pulse 96; swelling, redness of eyelids, and pain in swallowing, continue: five of the needles removed from wound, which appears to be united.

Ol. Ricini, ʒj.; repetat. Tr. Opii h. s.

23d.—Pulse 72; remaining needles and stitches removed; wounds have adhered; swelling of face diminished; pain in swallowing continues; bowels have been freely moved.

Aq. calida vulneri Vap. Aq. Calid. inhal. pro re nata.

25th.—In same state as yesterday, with addition of slight cough.

Tr. Opii, ʒij.; Mist. Mucilag. ʒij. M. Coch. parv. p. r. nat.

26th.—Patient was found dead this morning, without having been observed by nurse to be worse than at hour of visit yesterday.

27th.—Body inspected to-day: no morbid appearance in contents of cranium; edges of wound adhering; superior maxillary found entirely removed, and with it the whole of the malignant deposition; a small perforation in septum narium; the glottis œdematous, and, from the same cause, rima glottidis much diminished in size; unequivocal traces of acute inflammation extending down trachea; lungs gorged with blood; no appearance of disease in any of the viscera. State of blood-vessels, or their contents, not examined.

The sudden and unexpected death of this patient caused me much surprise and regret; the more so that, upon careful examination of the surfaces from which the maxilla had been removed, and of the viscera, no traces of the cerebriform deposition had been detected; and, therefore, had she recovered from the consequences of the operation, return of the disease was improbable, or at least would not have arisen by extension from the vicinity of the parts from which the maxilla had been removed. I was also the more anxious for her recovery, that the operation was characterized by some of the lookers-on as severe, cruel, and horrible. That removal of the superior maxilla is attended with much more, or even as much, pain as many of our common operations, say amputation, I am inclined to deny, and I am at all events positive it is not proportionably so often fatal as that frequently executed, and therefore

less impressive though very dangerous, procedure. It is from the disfiguration to the countenance during the operation, the inevitable violence required to crush through the connections of the bone, and to wrench it from its situation, the deep chasm which is exposed, the copious hæmorrhage, and the apparently threatened suffocation, that excision of the maxilla has been styled, even by members of the profession, as a "frightful operation," and as scarcely justifiable. But it rarely leaves any deformity: it can be quickly performed: some of the parts concerned in the operation are not very sensitive: it frees the patient from a lingering and certainly fatal illness; does not leave him deprived of any important function, and is therefore equally, if not more defensible, than many of our operative interferences; and we justly discard feelings from which we instinctively shrink, and follow the dictates of calm, and, as in this instance, humane decision, when we set aside considerations of even severe pain and great danger, when the life of the patient is at hazard.

There are better founded objections to the operation than its supposed severity, viz. the impossibility of always eradicating the disease, and occasionally, though I believe rarely, the fatal effect of our interference.

There are two causes, either of which may frustrate the intention for which we practise removal of the superior maxilla in malignant disease of the antrum:—1st. The state of the constitution; 2dly, the extent and connections of the diseased part.

That fungus hæmatodes, or cerebri-form degeneration or deposition, which under many different forms constitutes malignant disease of the antrum, is an affection often existing in different parts of the system simultaneously, has been frequently shown. In some instances it has exhibited itself in a new locality so soon after removal of the active and only evident diseased part, as to lead to the strong belief it had existed previous to the operation.

In other cases the patient dying from the effects of the operation, dissection has exposed the affection in an incipient or advanced stage, in some part or viscus, though attentive examination during life had failed to detect it. In numerous instances, however, patients

have recovered after operations performed for hæmatoid or cerebri-form growths; in some of the cases have remained free for many years, then becoming affected; while again others have survived for long life-times perfectly exempted\*. But, in addition to these facts, we possess proofs from analogy that diseases unequivocally general or constitutional, the part at the time principally diseased, to such extent as threatens destruction to life, being removed, the patient will enjoy long-continued health: we have almost daily proofs of this. A person of a strumous family, with strong characteristic appearances of that diathesis, which indicate either the existence or the capability of suddenly producing the morbid degenerations peculiar to that affection, arrives at adult age without its local manifestation. It may be asserted that up to this age the disease did not exist, but only the capability for its production; but it now shows itself in a form not to be mistaken, and to save life the state of the member in which it is situated necessitates amputation: the patient recovers, and, in a majority of cases, immunity from further attack is obtained.

Similar facts, though not so frequently, are observed in schirrus, in which, however, the local disease is capable of being conveyed into the system by absorption, and therefore operations are rarely useful, unless in the earliest stages of the disease.

The belief, then, that in malignant diseases, and in scrofula, the whole system is tainted, or, express it as we may, the entire solids or the blood are simultaneously, or capable of becoming simultaneously, affected, ought not to prevent us from operating, when the whole of the part in which the disease is at the time active can be entirely, and, so far as the operation is concerned, safely taken away.

This brings us to the consideration of the second cause which may frustrate the intention with which we operate in

---

\* The patient upon whom Mr. Douglas's first operation for removal of the maxilla was practised, remains in good health, nineteen months having elapsed. I amputated at the lower third of the femur sixteen months since in the case of a young woman, who had a medullary tumor interspersed with bloody cavities, occupying and destroying the upper cord of the tibia, and she remains well. In the woman whose case is described in this paper, no malignant disease was detected at any part of the system.

malignant disease of the antrum, viz. the extent and connections of the diseased part. We know that hæmatoid or cerebriform disease rapidly extends itself, but whether by constantly increasing deposition, or induction of peculiarity of action, and consequent change of structure, is open to discussion. It is certain, however, that if any of the morbid tissue is left after operation, it soon involves the adjacent parts, rendering the interference useless. The absence of much pain at its commencement often prevents the patient from applying until the affection has extended beyond the limits of the antrum; while the disease being rare the surgeon is not afforded opportunities for its recognizance, and a correct diagnosis is not formed often until too late to be useful. A source of frequent error, causing the disease to be neglected, is the elasticity of hæmatoid disease being confounded with fluctuation—a mistake the more likely, that the fungus often shows itself in the usual site of gum abscess, or it protrudes into the nostril, and is taken for and treated as polypus, as in the instance I have detailed. It will be apparent that it is only while the morbid growth is confined to the body of the bone or to the antrum, in either of which it may commence, that there can be any hope from removal of the maxilla, for the neighbouring parts are so irregular in their surfaces, contain so many foramina, and enclose such important organs, that if the disease extends to them, its thorough eradication is impracticable. All this is evident enough, but the difficulty consists in determining in a given case whether or not entire removal of the fungous growth be possible. Where it protrudes through the palate into the nose or inside of the cheek, and there is no projection or elevation of the eyeball, nor impairment of its functions, which latter circumstance would denote extension of the disease backwards, and no fulness in the temporal fossa, there is a strong probability of success from removal of the maxilla.

But the growth may extend in all directions, and yet may be still contained within the walls of the antrum, and be thereby capable of entire eradication. In these instances the whole bone expands and becomes attenuated by the pressure within, as it may fre-

quently be seen partially to do in the more favourable cases, anteriorly inside of the cheek, inferiorly into the mouth, where the thinner expanded shell may be felt crackling under the finger like parchment: the feeling of crackling is not, however, to be obtained as a guide where the tumor is covered by the eye above, or the temporal muscle and fascia externally; but for the reasons above adduced, and from the fact, as seen by Messrs. Douglas and Pring, that in the case I have described, though the tumor had passed into the nostril, had forced upwards and forwards the eye, raised the temporal fascia and muscle, and still no vestiges of it were detected on dissection, prove that we are justified in operating, even under such circumstances, though the certainty of entire removal be diminished by the risk of the growth passing through the parietes of the antrum, and involving the adjacent parts.

Another point of difficulty is the determination of the benign or malignant nature of maxillary tumors. When I reflect upon the many different species of hæmatoid disease, and their various appearances at different stages of their progress, I think positive decision as to their nature impracticable, even though assisted by sight and touch, the aids of which we can rarely obtain without first laying open the antrum, as I was obliged to do. And although we may be thus enabled to decide whether the growth be benign or the contrary, as it is always, we believe, attached to the *whole* surface of the membrane lining the antrum, or its osseous walls, or springs from the *body* of the bone, we suspect even mild growths can be rarely removed by merely opening the antrum, as they, also, soon destroy the osseous parietes by pressure, and become inextricably connected with the adjacent organs and tissues.

We are aware cases are on record where a cure has been obtained by scooping out the antrum; but a greater number can be produced where the practice failed; and when we consider the impossibility of deciding as to the mild or malignant nature of the growth, even after we have got it exposed, our ignorance whether it arises from the membrane only, or from the osseous walls of the cavity, or body of the bone, in which latter circumstance the

scoop, assisted by the cautery, will prove insufficient; we must conclude that extirpation of the maxilla, which can be effected without leaving much, or any deformity, is, in seemingly favourable cases, by far the safest practice.

I am not acquainted with any sources from which the average mortality by the operation can be ascertained; nor am I aware whether any general cause of the fatal result has been observed. Considering the violence done in the immediate vicinity of the base of the brain, we should, *à priori*, fear implication of that organ, or its membranes; and recollecting the wrenching of the maxilla from its osseous connections, and the tearing and cutting of its soft attachments, below which parts are suspended the important and easily excited trachea and œsophagus, we should almost certainly anticipate inflammation and its consequences in them, as the effects of the operation.

What we should suppose probable occurred in my case; and I have detailed it principally with the view of putting other operators on their guard, that they may use precautions to command incipient laryngitis, or obviate its danger if it progresses; as, had my attention been directed to the probability of its supervention, I would have employed more energetic treatment against the pain in swallowing, and the cough which existed—symptoms which did not excite surprise or alarm, being supposed inevitable, and not known to have portended danger in similar circumstances.

Watchfulness appears the more necessary, that in this instance the pulse did not indicate any risk, being only 72 at the hour of visit; the cough was trifling; the difficulty on deglutition not very great; and the patient, though seen by the clerk at 11 P.M. of the night previous to the morning on which she died, was not remarked to be worse than at the hour of visit. The night nurse asserted she did not observe any thing in the state of the patient during the night to excite her alarm; but it is quite likely she was not in the room, where the patient lay, from the time when she was so with the clerk at 11 o'clock the preceding night, until nine in the morning, when she found the patient dead; shewing the propriety of an attendant being con-

stantly with the patient for some time subsequent to the operation, lest symptoms of œdema glottidis present, when danger can be averted by performance of tracheotomy.

#### A REMARKABLE CASE OF SWELLED LEG.

By Dr. ULRICH, of Teplitz.

*With a Few Remarks on Teplitz,*

By Dr. DOMEIER.

DURING a three months' stay at Teplitz, in the summer and autumn of 1841, I had the pleasure of making the acquaintance of Dr. Ulrich, to whom I am indebted for the following remarkable case.

As this watering-place has been but little frequented by English invalids, it may not be disagreeable to the reader if I preface my translation of Dr. Ulrich's case by a few details respecting Teplitz.

It is situated in Bohemia, forty English miles south of Dresden, and fifty-five north of Prague.

The traveller will probably prefer one of these two routes—

1. From London to Hamburg by steamer; then by steamer up the Elbe to Magdeburgh; then by railway to Leipsic; again by railway to Dresden; lastly, by posting, diligence, or *Lohnkutscher* (*Voiturier*) to Teplitz.

2. From London to Ostend, or Antwerp, by steamer; then by railway nearly the whole way to Cologne; then by steamer to Mayence (sleeping, if the traveller likes, at Coblenz); then by railway to Wiesbaden and Frankfort; next by diligence to Leipsic—concluding as before.

The journey will last from seven to ten days, and cost about £12.

The route by Hamburg, though the longest on the map, will generally be found the shortest in time, as it is traversed by steam throughout, with the exception of the journey from Dresden to Teplitz.

Almost every house in Teplitz is either an inn or lodging-house; and decent, though not elegant accommodation, may easily be obtained. It is singular that a watering-place which has so long been the favourite retreat of kings and princes, should be so little

redolent of their presence, and so destitute of a palatial air; but the traveller, sated with the splendour of the hotels on the Rhine, may, perhaps, be pleased with the rustic simplicity of Teplitz. One curious deficiency I do not recollect to have observed elsewhere. Instead of a bell in each room, there is one in the passage, common to a dozen chambers. The unfortunate who wishes to summon a servant, goes out and rings the general bell, and then draws a moveable cover over the number which represents his apartment on a tablet suspended beneath the bell. The waiter, should he happen to come, thus learns where his services are wanted.

Perhaps the best-situated lodging-house in the town is the *Deutsche Haus*, overlooking the handsome garden of the *Herrenhaus*. It belongs to Count Ledebour, who retains the first floor himself, and lets the second at the rate of 6fl. C. M. (or twelve shillings) weekly, for each front room, and 4fl. C. M. (or eight shillings) weekly, for each back room. Sometimes the Count lets the first floor, or part of it, to a visitor of the highest rank; last season he granted this favour to the Duchess of Angoulême. There is a coffee-house on the ground-floor. The *Herrenhaus* is one of the principal bathing and lodging-houses, and is a very large mansion indeed. I lived in it for six weeks.

The suburb of Schönau is far more cheerful than the town of Teplitz itself; so that the invalid who intends to use the baths of the former, or who can come into the town to bathe without inconvenience, will do well to select Schönau for his residence. The season at Teplitz lasts from the beginning of May to the middle or end of September. How many persons use the baths of Teplitz annually? This is not easy to ascertain. The *Badeliste* for the 24th of September, 1841, now before me, gives 4569 as the number of persons with their attendants who had arrived up to the 22d inclusive\*.

Now if, on the one hand, we imitate

\* The number who had arrived up to the 4th of August was 3486, so that 1083 came in 40 days, or about 27 a day. In August the daily arrivals were probably double this amount. The titles appended to the names of the *Curgäste* have sometimes a tendency to length; thus, in the list of Sept. 24th, Herr Rohrmann is a Prussian *Oberlandesgerichtspräsident*; and the first lady who arrived at Teplitz in 1841 was an *Oberpostamtassistentin*.

Dr. Granville's rigour in his account of Baden, and erase from the list all who arrive, but do not bathe, we shall not lose many; for almost every one bathes, at least occasionally. But, on the other hand, how are we to count the myriads, who, though not of sufficient rank to find a place in the list, flock into Teplitz from every district around, and use the waters as a panacea? Besides the private baths for the upper and middle classes, there are six public ones—three for men, and three for women. They are frequented from four in the morning till nine at night, and the price of admission is extremely moderate. A paper was fixed on the door of one, stating the price to be three kreuzers of the Vienna standard for a woman, and two for a child, the highest of these sums being less than a halfpenny English. At a private bath, after paying extra for linen, and giving a handsome gratuity to the attendant, the grand total amounts to less than a shilling.

Amid all the changes of medical fashion, the baths of Teplitz have maintained their reputation for more than a thousand years, and this for the simple reason that they have constantly effected cures. They are of indisputable efficacy in gout, rheumatism, contractions arising from wounds, and a host of other maladies; so that, besides the great Austrian Military Hospital, the Prussian and Saxon governments think it right to maintain hospitals here for the cure of their soldiers. But if one wishes to have the statistics of their success, and learn whether Teplitz cures a greater proportion of cases than Bath, Wiesbaden, Baden, or Aix-la-Chapelle, I cannot tell where the information is to be found; the *méthode numérique* is still in its infancy, and we are left to conjecture or partiality.

The temperature of the principal spring in Teplitz is 122° of Fahrenheit; those in Schönau are from 99½° to 104°. The water has but little taste, and its solid contents are very small indeed; the chief one being carbonate of soda.

The medical staff at Teplitz last season consisted of fifteen physicians, seven surgeons, and one apothecary. The last has a monopoly. Physicians and surgeons practise where they please; but an apothecary, in Germany, must have a special license for the town where he intends to reside.

As Teplitz is out of the beaten track of English travellers, it is far quieter than many watering-places (those near the Rhine, for instance), and is, consequently, better adapted for some classes of invalids. There are no gaming-tables here, and few late parties; for those who bathe at five or six in the morning are ready to go to bed incredibly early. A theatre where the performance ends at eight, balls in the Garden Saloon, and excursions to the agreeable country around, are the chief amusements.

The *Jardins à l'anglaise*, or parks and shrubberies, in Teplitz and the neighbourhood, are extremely beautiful; the *Schlossgarten* or Castle Garden, behind Prince Clary's chateau, is the finest, and may vie with the best in Europe.

Perhaps it is an advantage that few books are to be found here; those who think otherwise will do well to bring a supply in their trunks. There is no banker in this place, and it is consequently advisable to bring a sufficiency of Austrian money, to escape the heavy profits of the money-changers.

English and French are not very current among the householders of Teplitz; German and Bohemian are the languages of the place. The former often deviates from the *Hochdeutsch*, or standard German, both in pronunciation and in the substitution of provincial words. Thus *heiss* is pronounced *hace* instead of *hice*; cream is called *Schmetten* (from the Slavonian *Smetana*) instead of *Rahm* or *Sahne*; and horseradish *Kren* instead of *Meerrettig*.

I might add much more on the modes of life current at Teplitz, and the sights which strike the stranger who has never before visited Bohemia. The Slavacks, for example—those singular wanderers, picturesque in abject poverty; or I might mention the classic elegance with which women of the lower orders dress their hair, giving this part of their costume the charm of a Greek statue\*; but I will no longer detain my readers from the interesting case narrated by Dr. Ulrich.

University Street, May 2, 1842.

CASE.—Frederica Könert, a servant,

\* Ordnete dann und flocht nach der Sitte der attischen Jungfrau;  
So wie Praxiteles einst und Phidias Mädchen  
des Himmels  
Bildeten.

Voss.-LUISE.

æt. 39, of lymphatico-venous constitution, does not recollect having suffered by any particular disease. She has had two children, with easy deliveries: the catamenia are regular. Several years ago, however, she began to feel pains in her right foot, which were sometimes stabbing, and sometimes tearing. They usually went off spontaneously, and left behind an insignificant swelling of the whole leg; but this, too, always speedily disappeared. During her last pregnancy, the pains in the foot were more frequent than before; and after a safe delivery (eighteen months ago) the foot became thicker throughout its whole length, and gradually attained its present state, when it is a real monstrosity.

Three months ago she came to Teplitz, and entered the hospital which is under my direction, when I found the foot as represented in the drawing; the

patella could hardly be felt. The swelling was firm. Three months' bathing has had no effect, except that the swelling at the knee, particularly the bend of the knee, is softer, and her walk consequently easier. She has had no medicines, as I merely wished to see the effect of the warm bath at 39° of Reaumur (1194° of Fahr.)

She has now left Teplitz, to seek for

aid in the hospital at Dresden, where she will be treated gratuitously, being a native of Saxony. I proposed the treatment by starvation (*Hungerkur*), or an active course of iodine or mercury.

D. ULRICH.

Teplitz, Oct. 12, 1841.

#### MEASUREMENTS.

1. Circumference of the left thigh, from the pubes to the inguinal region, towards the middle of the os ilium, and then back to the pubes, 21½ inches.

2. Circumference of the right thigh at the same place, 28 inches.

3. Circumference of the first break, 35½ inches.

4. Circumference of the second break, 38½ inches.

5. Circumference of the knee-joint, 30 inches.

6. Circumference of the calf, 23½ inches.

7. Circumference of the leg, three inches above the external and internal malleolus, 17 inches.

#### CURIOUS FACTS CONNECTED WITH GESTATION.

*Can the Male exert any influence on the duration of the Fetus in Utero?*

BY JOHN CHARLES HALL, M.D. F.L.S.

Fellow of the Royal Medico-Botanical Society,  
and Member of the Royal College of Surgeons,  
London, &c. &c. &c.

(For the Medical Gazette.)

FACTS connected with gestation are exceedingly difficult to obtain. In the human subject it is hardly possible to determine the precise number of days the foetus has remained in utero; this is well known to every professor of midwifery: in truth, every practitioner is aware that women are very frequently "out in their reckoning," and that the birth of the child takes place in but very few instances at the precise period laid down by the mother; days, and in some cases, even weeks, pass away, before delivery. It is, therefore, only under peculiar circumstances that the precise time can be clearly determined, as in the case related by Dr. Dewees, in his *Compendium of Midwifery*, where "a gentleman who had been obliged to absent himself from his family for many months, returned se-

cretly, and spent one night at home with his wife, in consequence of which she conceived."

The proposed question, as regards the human subject, is rendered more difficult of solution also, from a variety of circumstances which tend to mislead a woman in her calculation. In the case just quoted from the writings of Dr. Dewees, there was a regular return of the catamenia (a week after sexual connexion) in their usual quantity; and this induced her for some time to suppose that she had escaped with impunity. I might quote several other cases to prove that the absence of the menstrual discharge is by no means a certain diagnostic mark of pregnancy. I have more than once met with instances of menstruation occurring after conception had taken place, and others in which it was even more profuse during the first or second months of pregnancy. Johnson, in his *System of Midwifery*, says, "some have the menstrea copiously at the first period." "I have seen," remarks Desormeaux, "some cases in which the appearance of the menses in small quantities, and at an unusual time, was almost a certain sign of conception." The truth of this observation is confirmed by Gardien, Stein, and Puzos. Dr. W. F. Montgomery had a patient, the mother of three children, who informed him that she was always certain of conception "from the profuseness of the next period." Burton writes, "It is well known, by experience, that the menstrual discharge sometimes continues in its usual regularity for two or three months after conception, without any dangerous consequences;" and it is easy to appeal to other authors who would confirm the truth of this remark. It has been objected that these discharges are not menstrual: that is, however, a point foreign to our present inquiry, and therefore the discussion of it is declined: still I venture to observe, that if not menstrual, the discharge is so similar in colour and quantity, and takes place at such regular periods, that neither the woman nor her medical attendant can detect the difference. There are some few instances on record in which these discharges have continued almost during the whole period of pregnancy. Dewees records two cases, a mother and daughter, who were in

the habit of menstruating up to the seventh month. But what says Gardien, in his *Traité des Accouchemens*? "On a vu chez des femmes jeunes et pléthoriques l'évacuation menstruelle continuer pendant les trois ou quatre premiers mois, quelquefois même pendant tout le cours de la grossesse." (P. 489.)

It may be necessary also to mention those remarkable instances where menstruation has either appeared for the first time after conception, or only continued during pregnancy. Perfect's eighteenth case exhibits a curious example of the former; and Baudelocque and others furnish instances of women whose habit it was only to menstruate during pregnancy, and who did so regularly during its whole period, but at no other time.

It must also be remembered that cases occur in practice in which suspicion arises in connexion with a non-appearance of menses; their proper discharge being prevented by some peculiarity in the formation of the sexual organs, but more generally from the imperforate state of the hymen. Frank mentions two cases of this nature, in one of which the abdomen was as much enlarged as in the sixth month of pregnancy, and the female fancied a foreign body had taken possession of her uterus. The enlargement was produced from the accumulation of five or six pounds of dark blood, without any disagreeable odour. In the other case, the poor girl was exposed to temporary loss of reputation; but the hymen was found in the same condition as in the case just quoted, and, when punctured, gave passage to several pints of blood.

Another means usually employed for calculating the duration of pregnancy is equally uncertain: I allude to what is called quickening. I speak of this in the sense in which it is commonly used, for the English law considers the infant, before quickening, as *portio viscerum matris*; as though the spark of vitality was not equally sacred from the moment of conception—as though each process of gestation was unnecessary—as though the Almighty Governor and Creator could design that which was useless, or fail to perfect that which he had begun. In the words of Percival, "to extinguish the first spark of life is a crime of the same nature, both against our Maker and society, as to

destroy an infant, a child, or a man; the regular and successive stages of existence being the ordinances of God, subject alone to his divine will, and appointed by sovereign wisdom and goodness, as the exclusive means of preserving the race and multiplying the enjoyments of mankind." And another writer remarks, with equal force, "The law of the land is at variance with the law of nature, and it is at variance with itself; for it is a strange anomaly that, by the law of real property, an infant *en ventre sa mère* may take an estate from the moment of its conception, and yet be hanged four months afterwards for the crime of its mother."—(*Paris and Fonblanque*.)

In truth it is absurd to suppose, for one moment, that the foetus does not enjoy vitality from the first hour of its existence, and, of course, long before the sensation of quickening is felt by the mother; still it may be asked why indications of life are not given before the time at which quickening is generally said to take place? The obvious answer is, that the absence of this sensation on the part of the mother, as regards the motions of the child, is no proof that they do not exist, for the young foetus may, and in all probability does, move, and yet the parent be unable to distinguish such motions. Of this fact a modern writer (Dr. Montgomery) remarks that "he can speak with certainty."—"A married lady who menstruated for the last time on the 10th of November, came to Dublin in March, on the 21st of which month a consultation was held, to determine whether she was labouring under malignant disease of the womb or not, as she had been previously assured by her medical attendant that she could not be pregnant, 'because she had not sick stomach, nor felt the child.' On examination, the writer (Dr. M.) distinctly felt, through the abdominal parietes, the limbs of the foetus in motion, as did also Mr. Cusack and Dr. Marsh; and yet the lady herself had no consciousness whatever of any such sensation, nor did she quicken till the second week of the following month (April), and was delivered of a healthy boy on the 2d of August."

It is quite clear, therefore, that this symptom of quickening (which I suppose to be produced by the motions of

the child first being felt, and not, as Dr. Royston and others have imagined, to result from the sudden ascent of the uterus out of the pelvic cavity) is of little use in determining precisely the number of days a foetus has remained in utero; for in some cases the motion of the child can be felt by others and not by the mother, and in others it is equally notorious that the women have supposed quickening to have taken place even when conception had not taken place.

For other reasons sufficiently obvious, it will at once appear certain that we cannot supply materials from the human subject for answering, in a satisfactory manner, the question which forms the subject of our present inquiry—can the male exert any influence on the duration of the foetus in utero?

It is therefore requisite that we direct our attention, in the next place, to the inferior tribes of animals, and from them endeavour to derive the necessary information.

My attention was drawn to this subject more particularly a few weeks ago, during a professional visit to the Earl Spencer. His lordship has paid considerable attention to the subject of gestation, and has already written one or two papers replete with facts, I venture to assert, no other man in England could furnish. He asked me "if I thought the bull could exert an influence on the duration of the calf in the uterus of the cow, and if I could remember any work in which the author had mentioned this curious fact?" At the same time, he informed me that "one of his bulls seemed to exert some influence of this nature, for the cows in calf to him went some days longer than those in calf to other bulls." I replied, that I was not aware of any writer who had observed the same thing, and that I would mention the circumstance to a professional friend. I accordingly wrote to Dr. R. Lee, Lecturer on Midwifery at St. George's Hospital, and from him received the following answer:—

"My dear Sir,—The influence of the male parent in the duration of utero-gestation is a very curious fact, and I am not aware that it has been noticed by any one previous to you. I think it so important, that you ought, as soon

as you can arrange the observations, to publish the whole. I cannot find any allusion to the influence of the male parent upon the duration of pregnancy in the lower animals, by Tessier, and think it would be proper, before stating this, to consult his papers. I am very much engaged at present, but hope soon to be sufficiently at leisure to render you any assistance in my power; the doing of which will afford me the greatest pleasure. I have mentioned the fact stated in your letter to several friends, and they have all been very much struck with it.—I remain, my dear sir, with every kind wish,

"Yours very truly,  
"R. LEE."

On receiving the above letter from Dr. Lee, confirming the opinion I had before expressed to Earl Spencer, I requested his Lordship to furnish me with a statement of the facts he had observed. He kindly did so, and I now give them in his lordship's own words:—

"Upon taking," writes Earl Spencer, "an average of seven hundred and sixty-four different periods of gestation of cows, I found that two hundred and eighty-four, or two hundred and eighty-five days ought to be considered the usual period. The male animal by whom the cow was impregnated did not appear to have any influence, up to the time at which this average was taken; but in the autumn of 1840, I bought a bull, which I had sold as a calf in the spring of 1836, and the calves by him were first dropped in the beginning of last August; since then I have had sixteen calves by him, and to my surprise have found that the average period of gestation of the dams of these sixteen calves was two hundred and ninety and a quarter days. Upon this I applied to the gentleman who had bought the bull from me, and from whom I had bought him back, to let me have the period of gestation of each of the cows who bred calves by this bull, while he had him in his possession, and he sent me an account of the respective periods of the gestation of fifty-nine cows in calf by this bull; and I find, that the average period was two hundred and eighty-eight days; and if you add to the periods of gestation of these fifty-nine, the periods of gestation of the sixteen which have occurred since he

has been in my possession, the average of the whole seventy-five is two hundred and eighty-eight days and a half.

"It appears therefore quite clear," continues his Lordship, "that cows in calf to this bull, on the average, are about *four days longer before they calve* than those in calf to other bulls. It appears also that of the 764 cows on which I formed my average in my own herd from a great many different bulls, 185 went less than 281 days, while not one of the 75 cows in calf to this bull have done so. On the other hand, of the 764 cows 111 went above 289 days, or rather more than one-seventh of the number; while by this bull 29 out of the 75 went above 289 days, or between one-third and one-half."

Since the above was written his Lordship has given me the average period of gestation in 931 cows in calf to other bulls; and of 79 cows in calf to the bull in which this peculiarity was first observed, from which it appears perfectly clear that the duration of pregnancy in cows put to this animal, is, on an average, *four or five days longer* than in other bulls. This being the case, it is impossible to account for the fact in any other way than by answering the question proposed at the commencement of this investigation affirmatively, and by concluding that the male can influence the duration of the foetus in utero.

I shall now mention some other facts proving the influence of the male, independently of the female, over the functions of the uterus, and which appear further to strengthen the position I have already endeavoured to maintain

"*Causa statet vis est notissima.*"

In the present advanced state of science it is almost unnecessary to observe, that conception can take place without the knowledge of the woman. The question to be considered is this: can a woman become pregnant in consequence of intercourse of the occurrence of which she was not aware, and thus, finding herself with child, be quite unable to account for it? This at first sight may be considered as quite impossible; nevertheless, as before stated, this fact is established too fully to admit a doubt. Burns remarks "that so absurd a notion, as that conception evidenced consent, should in modern

times have obtained amongst any whose education and intellect were superior to those of an old nurse, is indeed surprising; at this day, however, facts and theory concur to prove that the assentation of nature in this respect is no ways connected with volition of mind." Experience, in fact, has more than once taught that a woman may become with child while in a state of hysteria, under the influence of narcotic poisons, during asphyxia or drunkenness, or during sleep, and therefore, without being conscious that sexual intercourse had taken place. Capuron has recorded an instance of this nature in the person of a young woman got with child while buried in a deep sleep, produced by her drinking freely of some punch which had been given her by the person who caused her ruin. This opinion is supported by Foderé, MM. Marc, and Raige Delorme, as well as by a more recent authority, Dr. Montgomery. Dr. Gooch says, "it is not necessary that the woman should be sensible at the time of impregnation."—"A *maid* at an inn, who was always thought to be virtuous, and bore a good character, began to enlarge in a way which excited suspicions of pregnancy; she solemnly declared that she never had connexion with any man. At length she was delivered, and was afterwards brought before a magistrate to swear to the father, but she repeated her former declaration. Not long afterwards a post-boy confessed that he came one evening late to the inn where the poor girl resided, that he put his horses into the stable and went thence into the house, the inmates of which were all in bed except this girl, who was laying upon the hearth-rug buried in a deep sleep. He contrived to gratify his desires without waking her; and this shews that impregnation may take place without the knowledge of the female."—*Compendium of Midwifery*, pp. 81-2.

Speaking on this subject, a very great authority (Beck) remarks:—"In females habituated to sexual connexion, or where sleep is unnaturally produced, there is no doubt of conception occurring without the knowledge of the female:" and he mentions a very remarkable case in a note, confirming this opinion.

Not to extend this paper by multiplying cases, I shall conclude by men-

tioning the very remarkable one quoted by Bruhier, Foderé, Montgomery, and others from the "*Causes Célèbres*," which proves that the female can be impregnated during a state of complete asphyxia or apparent death.

"A young friar being on a journey, arrived at a house where they were about to bury a young girl, whom they believed to be dead. He proposed to pass the night in the chamber with the coffin, and watch the body. In the course of the night, whilst examining the body, his passions were so excited by the beauty still remaining, that he determined on satisfying them even under such circumstances. He departed early the next morning, and in the course of the day the apparently dead revived, proved to be pregnant, and at the end of nine months brought forth a child to the great amazement of her friends as well as her own. The friar returned to the place about this time, confessed himself the father of the child, and married the mother, having procured absolution from his vows, which he had taken against his will."

It appears, then, from the above facts, that the male can impregnate the female at a period when the latter is in total ignorance of it; and it also appears, from the facts which I have mentioned in the former part of this paper, and which I believe are now brought forward for the first time, that the male can influence the number of days the foetus remains in utero. This, as Dr. R. Lee observes, "is a very curious and a very important fact;" and it will be for other physiologists carefully to inquire into it. I shall, as a matter of course, keep my eye upon the animal here particularly referred to, and see if he continues to influence, as now, the period of gestation. At present it appears quite clear that if a cow becomes impregnated by him, the duration of the foetus in utero will be some days longer than the usual time.

Retford, March 24, 1842.

### HYSTERIA IN A MAN.

*To the Editor of the Medical Gazette.*

SIR,

THE perusal of a case of "Hysteria in a Man," related by Mr. Smee in a recent number of the MEDICAL GA-

ZETTE, called to my recollection a somewhat similar and, I think, equally interesting case, which fell under my notice some months ago, in the Union poor-house of this town.

If you think it worthy a place in your valuable journal, I shall feel obliged by its insertion.—I am, sir,

Your obedient servant,  
G. E. STANGER.

Nottingham, April 19, 1842.

Abel Simons, æt. 19, a robust-looking man, but somewhat deficient in intellect, being one of that class to whom the sobriquet of "*soft*" is vulgarly applied, was seized, soon after eating a hearty dinner, with a violent fit. I was called to him immediately, and found him struggling violently, and held down by five men, who were endeavouring, *vi et armis*, to prevent him from injuring himself.

I was struck with the absence of those symptoms which characterize true epilepsy, and remarked that the same phenomena occurring in a female would, with little hesitation, be set down as a case of violent hysteria. There was no lividity or turgescence of countenance, no foaming at the mouth, nor was the tongue bitten. The pulse continued natural, and the pupils were neither dilated nor contracted. The eyes were in constant motion, and the whole body was kept in violent convulsive action, apparently so long as the strength would allow. He would then remain quiet for a few minutes, and after a longer or shorter period the same violent motions would recur.

The first fit occurred on Tuesday morning. As he was a young man of full habit, and was accustomed to eat enormously, I abstracted 16 ounces of blood from his arm, applied cold to his head, administered an active purge, and ordered him to be restricted to water-gruel.

Notwithstanding these measures, the fits continued, with slight intermissions, until Wednesday night, at which time Dr. Davidson saw him, and concurred with me in the belief that the fits were, in a great measure, under the patient's control. Dr. D. observed, that when he was going to have a fit, if he told him to remain quiet for a short time he would do so. Dr. D. recommended me to attempt to act powerfully on the man's imagination by threatening him

with some very violent remedy, and suggested the trial of a hot poker for that purpose.

Accordingly, on Thursday morning, finding that he had been in fits all night, and had tired out his attendants by his violent struggles, I called the nurse to his bed-side, and desired him to have a poker kept red hot in the fire, and as soon as the fit came on to apply it to a specified part of the back. I added, that though this was a severe measure, and would cause intense pain, it appeared to Dr. Davidson and myself as the only means of curing his malady.

This was said in the hearing of the patient, and, as was anticipated, he never had another fit. On two or three occasions he was on the point of *going off*, but before the poker could be brought to the bed-side, all convulsions had vanished.

I believe that cases somewhat resembling the above are by no means uncommon. They may not present precisely the same features: these may be variously modified, according to the previous habits of the individual, and a variety of contingent circumstances.

It may be difficult to determine the precise pathological condition on which such affections depend. It is not improbable that some morbid condition of the digestive organs in the male, as of the uterus in the female, acting upon a mind little accustomed or able to control its emotions, may account for the disease in question. At any rate, the malady, in both sexes, can scarcely be considered as purely mental or purely physical, but rather as made up of a derangement of both body and mind; and therefore requires a treatment partly moral and partly medical. It is scarcely necessary to remark that we should be on our guard in the management of such cases, and carefully distinguish them from some graver diseases with which they might be confounded.

## ON RESPIRATION.

FROM THE GERMAN OF RUDOLPHI.

BY THOMAS S. BECK,  
Lecturer on Surgery in Sydenham College,  
London.

(For the Medical Gazette.)

If the individual doctrines of the old and new physiologists be compared,

probably there is none in which a greater difference of opinion is remarked than in the doctrine of respiration. A fault very generally committed on one side was, that of considering the vault of the chest, with its muscles, as active; the lungs, on the contrary, as passive: nor was the activity of the larynx and trachea, so very remarkable, at all taken into consideration. On the other side, the peculiar aim of respiration was mistaken, viz. to change the venous blood into arterial, and to support the animal heat. With regard to the first point, it might be maintained that, at present, we understand the mechanism of respiration, and the structure of the co-operating organs, as well as any part of the animal economy; and, in respect to the second, there appear only some points of less importance which remain very doubtful; so that, in truth, we must not reject the examinations of the natural philosopher and the chemist; nor must we content ourselves with the common-place, and, therefore, meaning-less expression—respiration is a vital action; by respiration the blood is idealised; &c.

The organs of respiration may be conveniently divided into external and internal, or into auxiliary and essential. In the animal kingdom the latter remain after the former have long ceased to be found, although, in the lowest animals, they at times appear blended together.

The essential or internal organs are the larynx, the trachea, and the lungs; the external or auxiliary organs, the nose, the mouth, the vault of the chest, and all parts contributing to its change.

In animals breathing by lungs the air is commonly drawn through the nose. We see the play of the nostrils especially in the amphibia; but also in birds. In the mammalia, we not unfrequently see the alæ of the nose become most violently moved after exertion; and there are several in this class that can only breathe through the nose—as the race-horse, the elephant, and the cetacei. Man, with a perfectly free nose, breathes through it when asleep; but with the passage of the nose somewhat obstructed, respiration takes place by the mouth remaining open: thus the velum palati trembles, and there arises an unpleasant snoring (stertor). But, on the contrary, respiration can go

on by the mouth alone; and I have already mentioned some examples in man, where the posterior nostrils were entirely closed, so that respiration was only possible through the mouth.

To what extent the opening of the mouth stands in connection with respiration in man, is seen by gaping (oscitatis) after weariness, or any difficulty of breathing. Here the mouth is strongly opened, and long kept open, during which the larynx and the chest are widened, in order to inspire strongly and deeply; after which a strong expiration takes place. We also see the connection in the last respirations of the dying, as well as in the attempts at resuscitation; when, if it entirely or partly succeeds, a slight opening of the mouth occurs, then a gaping, or, as we usually call it, "snapping after air." Now and then all our endeavours are unable to produce more than a gaping similar to that with which life is entirely extinguished. This readily explains the first respiration; for from the unpleasant impressions to which children are exposed during birth, and immediately after it, their facial muscles begin to move; the mouth and nose open, and involuntarily draw in air, so that a cry is excited: the same happens if they come into the world asphytic; when, by shaking, or some light strokes, we call them into life, so that they breathe and cry.

These movements evidently stand in connection with those by which the cavity of the chest becomes expanded, and upon which others again follow which contract it. The powers which contribute to the movements are very manifold, and are only collectively called into action in cases of the greatest necessity.

The expansion of the chest, in the first place, is occasioned by the ribs becoming raised upwards and outwards, by which the sternum is also moved forwards; whilst, secondarily, the diaphragm contracts, and thereby descends. By these movements the long and transverse diameter of the chest becomes enlarged, i. e. from one side to the other, from the front to the back, and also the oblique measurement. The front rib, which is firmly bound to the sternum by a short cartilage, and more firmly fastened than the other ribs by the scaleni and other stronger ligaments, is to be looked upon as the fixed point

towards which the other ribs are drawn and rolled forwards and outwards, so that the sternum must necessarily come forward. This is principally effected by the intercostal muscles, as well by the internal as the fibres of these muscles crossing each other: their power must be considered as acting diagonally upwards: the second rib is already freer than the first, which is the same with others, so that they progressively become easier raised. If the customary enlargement of the chest by the intercostal muscles be not sufficient, the greater and lesser pectoral, the anterior and superior posterior serrati, and indirectly the several muscles of the vertebral column and scapula, contribute to the expansion of the chest.

The action of the intercostal muscles opposes the contraction of the cavity of the chest; but the last-named muscles, on the contrary, are opposed by the latissimus dorsi, the inferior posterior serrati, and several muscles of the vertebral column.

With these muscles serving for the expansion of the chest, the diaphragm now co-operates most powerfully. It contracts from all sides towards the centre, by which it descends, becomes flat, and presses the abdominal viscera downwards and forwards. The abdominal muscles which are opposed to its action draw the ribs downwards and themselves inwards, thus narrowing the abdominal cavity, and pressing the viscera up towards the relaxed diaphragm.

In the child and in the woman the mobility of the ribs, &c. is very great; and we see, when they are perfectly quiet, or asleep, how their chest rises and falls. In man, whose chest is more capacious, and therefore ordinary respiration requiring no great expansion, that movement is much less seen; so that, for the most part, the alternate action of the diaphragm and abdominal muscles appears to be sufficient.

Obs. 1.—Whilst the amphibia draws in the air through the nostrils, it is conveyed, by the incessant movements of the membrane of the throat, to the open glottis, and is received by it: hence the movements of the throat are much more frequent than those of the nose; and bear the proportion to them of three to five, or even of seven to one. However, we must not estimate the number of respirations according to

the former, with Townson (*Observations Physiological de Amphibiis de Respiration*, Gott. 1794), by which he arrived at a false position, viz. that the amphibia inspire more frequently than the warm-blooded animals.

Herboldt maintained that the mouths in frogs must remain hermetically closed when they breathe; and that if their mouth be held open by a small ring or a piece of wood, they soon died. The Philomatic Society in Paris (*Bulletin*, An. 7) repeated these experiments, and found that the animals died in a few minutes if their mouths were not hermetically closed. I thought this very improbable, and repeated the experiments in a variety of ways in the same year; and found that frogs continued to live perfectly well, with their mouths open, hours, days, and weeks. I cannot think otherwise than that Herboldt and the Philomatic Society have placed their animals with the mouth open, in water, where they certainly must soon be drowned; instead of which I kept them in a box, placed in the garden, in the open air.

Obs. 2.—Sir C. Bell (*An Exposition of the Natural System of the Nerves*, London, 1824-8) has justly connected the movements of the countenance, in the emotions of the mind, with those of respiration. If some have been too strongly expressed by him, those who pay no attention to this will not be able to form any complete idea of breathing in general, especially of the first respiration, and of the modifications of respiration from the emotions of the mind.

Obs. 3.—It is a mere paradox, when Magendie, contrary to Haller and all other anatomists and physiologists, admits the movement of the first rib to be greater than that of the following; for if he only undertakes to examine, without prejudice, the ligaments and muscles of the first rib, he must immediately retract his false views, which can only have arisen in the study, or in a transitory observation of an artificial skeleton. Whence comes it that the first rib so very often morbidly adheres to the sternum, if it be not because it lies almost immoveable upon it; whilst the sternum and clavicle are scarcely ever ankylosed, from the movement between them being greater?

Obs. 4.—The movements of the chest in the mammalia are probably exactly

the same as in man; and we see this in a very strong degree in the so-named "beating of the flanks," especially in the horse. In all, the diaphragm and abdominal muscles perform the same functions; but not unfrequently the cartilages of the ribs become ossified very early, by which they resemble birds; in whom, as far as I know, it is without exception. In our museum there are skeletons of the ornithorinchus; of the three-toed sloth; of the ant-eater; *myrmecophaga jubata*; *tetradactyla*, and *didactyla dasypus sexcinctus*, of two vampires, of a couple of opossums, of an old *dispus sagitta* (for in the other skeletons of *dipus* and *meriones* it is not), of an old mole, and of *chrysochlorus*, which are provided with intervening bones instead of the cartilages of the ribs. In some of the last named animals the ossification appears not to have occurred so early as in the others. The difficulty of the cartilages of the ribs (except the first) becoming ossified in man is generally known. Indeed, we have the example of Thomas Parr, who was a hundred and fifty-two years and nine months old; and in whose body the renowned Harvey found those cartilages unossified. The whole of this remarkable dissection is found in *I. Bettus de Orta et Natura Sanguinis*. London, 1669.

[To be continued.]

#### FURTHER NOTICE CONCERNING THE AMMONIACO-TARTRITE.

*To the Editor of the Medical Gazette.*

SIR,

ABOUT ten years ago I introduced to the notice of the profession in your valuable journal (*MEDICAL GAZETTE*, No. 187, July 1831,) a preparation of iron somewhat differing from any hitherto employed, which appeared to me to possess some useful properties almost peculiar to itself. The salt is the ammonio-tartrite of iron, or tartrite of iron saturated with ammonia, forming a triple salt of pretty uniform composition; and I described the method of preparing it, which, with moderate quantities, is simple, easy, and, as far as I find, unfailing. It was suggested to me by an observation in Klaproth's *Essays on Mineral Analysis* (that mine

of valuable information to the practical chemist), that the presence of a certain proportion of tartaric acid in any of the solutions of iron entirely prevents the precipitation of the metallic oxide by any alkali, pure or carbonated, and in any excess. Now as several of the most useful salts of iron have the inconvenience of letting fall part of the metal either as a peroxide or a sub-salt on saturation with alkali, or exposure to air, or even by long keeping, the tartaric acid suggested itself to me as the most useful medium for preserving this metallic oxide unchanged for medicinal purposes. But the simple salt of oxide of iron and tartaric acid when in mutual saturation, forms a tasteless mass, nearly insoluble in water, and only to be exhibited in the form of powder, which much limits its utility. This is avoided by saturating the tartrite of iron with ammonia, in the manner I have described in my first notice. The triple salt thus obtained is a uniform red brittle uncrystallized mass, which does not deliquesce in the open air, and which dissolves most readily and copiously in distilled water into a blood-red solution, the clearness of which is not disturbed by alkalies or alkaline salts, and, with the help of a little spirit of wine, will keep unchanged for a length of time. It has a strong, not unpleasant sweetness of taste, much resembling that of liquorice, which nearly overpowers the chalybeate, and in general is highly palatable to young children—an advantage which is not to be despised when a course of tonic medicine is to be persevered in with these capricious subjects. It also mixes very well with porter, when, as is often the case, this valuable domestic tonic is called into aid.

But the object of my present notice is to state, that I have also long found this salt to mix, without visible decomposition or deposition of oxide, with both the tincture of iodine and the ioduret of potassium; and this appears to me to supply a formula for a compound still wanted, and which is done with difficulty in using the otherwise valuable ioduret of iron introduced to practice by Dr. A. T. Thomson. The respective solutions of the ammonio-tartrite of iron and of the preparation of iodine, whichever may be preferred, may either be kept separate till the time of making up the prescription, or previously mixed,

in any required proportion, in a phial with a *glass* stopper (not cork), and added to any simple water, or to decoction of sarsaparilla, for example, or to a variety of other articles of the Pharmacopœia.

I may add, that as my first notice of this salt was made before the publication of the last edition of the Pharmacopœia Londinensis, the editor was inclined to introduce it; but he preferred the analogous salt of tartrate of iron and potash, I believe, as being prepared in the large way with more ease than the ammoniacal salt. The present potassio-tartrite of iron is equally miscible with alkalies without decomposition; nor is it disturbed by the salts of iodine; but it has not the sweet liquorice taste of the other, and, what is of more importance, it is highly deliquescent; so that it cannot be employed in the form of powder, and the weighing of it is attended with some little inconvenience.

The effect of sugar in depriving metallic solutions of oxygen, wholly or in part, is well known to chemists. Thus the acetite of copper, boiled with sugar, gives a brown protoxyd of copper; sulphate of copper, in like manner, lets fall part of the metal in the metallic state. The salts of iron may long be kept, by this means, in low oxidation, and by the assistance of tartaric acid may be saturated with alkali without apparent change.

In this way a very useful *syrupus ferri* may be prepared with great ease, thus:—

In a Wedgewood evaporating dish dissolve 80 grains of sulphate of iron and 40 grains of acid of tartar in an ounce and a half of distilled water. Add liquid caustic ammonia, which first gives an olive-green precipitate that redissolves by a small excess of the alkali, to a clear grass-green liquid. Evaporate this slowly, nearly to dryness; then redissolve in water, with a few drops more of the alkali, and make up the quantity to a fluid ounce and a half. Add to this two ounces of sugar, and boil briskly for a minute or two, and the syrup is made. These quantities furnish about two ounces and a half of a very dark, clear, hair-brown syrup, which readily dissolves in water without becoming turbid. The syrup may be made in one vessel in a very short time; and it appears to keep for

an indefinite length of time without fermenting or changing in any way. In the proportions here given one drachm of the syrup contains four grains of the sulphate of iron mixed with tartrate of ammonia.—I am, sir,

Your obedient servant,  
C. R. Aikin.

7, Bloomsbury Square,  
May 1, 1842.

### LANCET WOUNDS—PHLEBITIS.

*To the Editor of the Medical Gazette.*

SIR,

NEARLY two years have elapsed since a fatal case of phlebitis occurred to me. A short time previously another fatal case occurred—both in Malta. Whether any peculiar state of the air had an influence in producing the malady, I do not know; but in the case to which I particularly allude, the patient had for several years laboured under symptoms of angina pectoris, and been repeatedly bled for paroxysms of that disease. His habits were intemperate, and he had been complaining of a peculiar pain and anxiety in the region of the heart for several days, when I was induced to abstract a considerable quantity of blood from the arm—means which had previously afforded him decided benefit. The blood flowed in a very full stream, and it was found impracticable to check the hæmorrhage by means of the ordinary sized compress and bandage. The roller therefore was applied more extensively, so as at length to suppress the bleeding. He was relieved by the operation; and as no complaint was made of the arm, it was not re-examined till about a week afterwards, when the patient, who was hospital sergeant of 59th regiment, complained of pain in the site of the wound. Upon examination it was found to be irritated and slightly inflamed, with tumefied edges, but not to a greater extent than I had before observed in a vein without producing any serious inconvenience. Some diaphoretic medicine was prescribed, and simple dressing applied to the wound. Next morning violent rigors supervened, which were followed by unequivocal symptoms of phlebitis. Leeches were numerously applied to the bend of the arm, and

753.—xxx.

mercurial medicines administered, with fomentations from the hand upwards; but in vain: the disease rapidly ran on to a fatal termination.

I have not the notes before me at present, and therefore can give no detailed account of the case; but the question I feel constrained to ask is, whether the mischief may not have in part originated in undue pressure upon the vein, from the bandage not having been carried up from the fingers, but merely being placed round the elbow-joint, in a person predisposed to disease of the vascular system, and where the *vis medicatrix nature* was too weak to repair even a slight solution of continuity. I have invariably, since this unfortunate case, taken particular care to examine the lancet wounds after bleeding, and to dress them appropriately every day till suchtime as union may have taken place; and I would consider this practice more essential where there is difficulty in arresting the hæmorrhage, which would appear to arise from impaired vital properties. I hope this hasty communication may be of service in attracting the attention of my younger brethren to lancet-wounds, and induce them to pay the utmost attention to them in every case, but particularly in unhealthy constitutions.—I am, sir,

Your obedient servant,  
J. MAIR, M.D.

London, April 30, 1842.

### THE CHIGOE, OR GIGGER.

A FRAGMENT FROM A DIARY KEPT IN THE  
WEST INDIES,

BY FREDERIC ROBERTS,  
Assistant-Surgeon 59th Regiment.

(For the Medical Gazette.)

As medical authors give no account of the chigoe, which becomes so often parasitic to man, and a source of considerable annoyance to him in the West Indies, and as it has further been doubted to be an insect, the following short paper, containing the slender information that could be gathered from a few examinations of cases, respecting the habits, effects on the body of man, and treatment for its removal, is offered.

The "chigoe," or "chiego," of the

West Indies, and the "pulex penetrans" of naturalists, consists of two species, the *black* and the *white*, in the natural history of which there appears to be no difference. The habitation of the "gigger," as it is likewise called, is in stables, kitchens, and on the ground in the open air in dry weather, which is the season it mostly prevails in—that is, from December to July. It attaches itself to the feet of those who walk about bare-footed, and those whose occupations are in kitchens, abounding in ashes and other filth. Holes in boots or shoes render one liable to be attacked by them. Its intrusions are not confined to the human species, but it is found to attach itself to cats, dogs, sheep, and still more to pigs.

The parts of the body it is found in are the soles of the feet and toes, and occasionally the fingers. It insinuates itself underneath the skin, and there deposits its eggs in a nidus of a tough gelatinous substance. Attention is first drawn to the presence of these insects by a gentle itching, which, as the insect insinuates itself deeper, and the nidus begins to grow, becomes, in a few days, less tolerable. The nidus, containing longish-shaped white gelatinous eggs, is a cyst of a tough membrane, and arrives sometimes to the size of a pea before the eggs are hatched, after which the new being likewise insinuates itself into the skin; so that in those who neglect extracting them there are clusters, buried under the skin of the soles of the feet and toes, which raise it in little round eminences, and create irritable sores, oozing a serous fluid, and ultimately intractable ulcers—nay, the entire toe has been known to be lost by the creeping ulceration that is established. The *black* gigger differs so much in its effects from the *white*, to which, it has been said, it otherwise resembles, as to be called the *poisonous* gigger, and produces much more malignant sores. The treatment for the removal of the chigoe consists in extraction by means of a needle—an operation dexterously performed by the negroes, and free from pain.

Regent Fort, Jersey, April 25, 1842.

## INJECTION OF AIR INTO THE EUSTACHIAN TUBE.

*To the Editor of the Medical Gazette.*

SIR,

SOME few years have now elapsed since the operation of injecting air into the Eustachian has been brought before the public: indeed it has been performed, or at least has been *attempted*, on some hundreds of individuals in this metropolis, and yet not a single case has been essentially and permanently benefited by it. Some have stated that they *thought* they had seen benefit from it, but it could not be positively affirmed; while the evils resulting from its application have been sufficient to render us exceedingly cautious in advising any patient to submit to it.

Amongst the bad effects produced by this air-douche may be enumerated inflammation of the throat and Eustachian tube, and also of the tympanum, which is sometimes so severe as to terminate in suppuration; emphysema, caused by laceration of the mucous membrane of the Eustachian tube, or of the posterior nares; rupture of the membrana tympani; deliquium, which, in some instances, has continued so long as to threaten life; and even death itself has occurred before the instrument could be removed which produced so awful a calamity.

When consulted by a patient as to the expediency of his submitting to this operation, these facts should be fairly and faithfully considered; and as most men in London must have seen sufficient to convince them of the inutility of the air-douche, it will be but prudent to advise a patient of its disadvantages and risks. Aware that some extraordinary effects have been reported from the north, yet viewing cautiously itinerants' wonders, and suspiciously the details of *medical* statistics, in *non-medical* works, we pass these by.

Probably some will read these remarks who have themselves undergone, or have believed they have submitted to, this operation, and may regard the dangers just detailed as imaginary, or to have been the result of want of manual dexterity; but these accidents have occurred in this country as well as in France and Germany, and it were

much to be wished that those who have advocated the advantages of this operation would be sufficiently candid to detail its evils.

We all know with how much zeal new medicines and new operations are seized upon by medical men; and to hear the accounts of these novelties, one would imagine that all diseases must speedily succumb to these enlightened, because modern, discoveries; but a few months roll away, the charm is dispelled, and the ephemeral improvements are forgotten.

This operation of injecting air into the Eustachian tube has been tried, and that, too, extensively, both in this and other countries; and with what result? Scarcely any but that which was injurious. In the *MED. GAZETTE* will be found the minute details of some cases, which should carry conviction wherever those statements are read. Itard has found it altogether useless: and when employed by Deleau himself, it produced the opposite effects to those he had intended.

Aware that many persons are said to have been cured by this air-douche, I would ask whether any new remedy was ever brought forward which had not been supposed to have cured numerous individuals. These patients themselves believed they were cured *by the operation*, because they regained their hearing; but the cause of their deafness might have been temporary, and might probably have been removed by the application of a blister and a little aperient medicine. But the patient is surely not a person the best capable of estimating the particular disease of the ear under which he laboured, and whether the operation he had undergone was essential for the cure of his particular case. We all know how frequently a patient fancies he sees the good or bad effects of a placebo; and admitting this, it is not difficult to imagine that patients may be mistaken respecting the effects of this air-douche.

It will be well here to review this operation. The air-press has not been inaptly compared to the air-gun; in fact it is constructed upon the very same principle: there is a condensing syringe and a reservoir, to which is attached a flexible tube with a stop-cock; and, in fact, upon this stop-cock depends the life or death of the patient undergoing the operation. This

is not mere matter of opinion, but is well known as matter of fact; that is, patients have actually died from too sudden and too large a quantity of condensed air being allowed to pass through the stop-cock of the flexible tube just described. A small silver catheter is passed through the inferior meatus of the nose into the Eustachian tube, and to it is accurately fitted the long flexible tube, so that a direct communication is effected between the Eustachian tube and the condenser. Sir John Robison, of Edinburgh, has been exerting his mechanical ingenuity to remedy the uncontrollable escape of condensed air from this dangerous apparatus; and Sir John himself considers he has overcome the difficulty, but others are of a different opinion.

Now what are the cases in which it is proposed to employ this air-douche. Most frequently it is advised when the Eustachian tube is imperforate; whether this canal has been temporarily or permanently obliterated by hardened mucus, or by repeated attacks of inflammation. If any other mucous canal, such, for instance, as the urethra, were partially or completely closed, is the injection of air the means we should employ to remove this stricture, or to subdue any inflammation which might still remain? If we had recourse to any mechanical means, should we not with much more propriety inject warm water? And why should we not employ the same treatment in removing an obstruction in a tube lined by a similar membrane?

It may be thought from these remarks that I advocate the injection of warm water into the Eustachian tube in all cases where it is closed; and sorry should I be if such an inference were drawn, because I am more and more convinced that operations of any kind are seldom of any use where deafness has continued for any great length of time.

I may perhaps be censured for stating that most of the cases of deafness which have come under my care have resulted from the negligence of the practitioners under whom the patients were placed when they first evidenced symptoms of deafness. Nor can I be surprised at this when I know that few of the surgical lecturers ever even advert to the subject, nor do the pupils interest themselves in any aural investigations.

Medical men have made up their minds that nothing, or next to nothing, can be done for deafness; and when a case devolves on them, they either treat it empirically, or at once send the patient to a professed quack, seldom taking the trouble to accompany him for a consultation, as they would readily do were the same patient's heart or lungs affected; and although we could scarcely put the one in competition with the other, yet it must be confessed that deafness is too great an evil to be so lightly regarded.

Of the cases of deafness which have come under my notice, a great majority have been the result of partial or complete obstruction of the Eustachian tube; and in most of these cases the patients have suffered severely from scarlet fever, or from a chronic inflammation of the fauces with enlargement of the tonsils. Now these two affections have caused more than two-thirds of all the cases of deafness which I have seen; and it is in the early treatment of such patients that the negligence to which I just adverted is so unhappily evidenced.

When a patient is convalescing after scarlet fever, he frequently complains of deafness, which, it is generally presumed, will "go off" as the patient gains strength; and frequently the hearing does return, but very often it does not. The remedial means usually adopted in such a case consist in the administration of bitters, the use of an astringent gargle, and in some few instances a blister has been ordered behind the ear; and even with this simple treatment some cases get well, which possibly would not had no such means been adopted. But surely when the inflammatory sore throat has been severe, and when the tonsils are nearly doubled in size, and offer either that hard and cartilaginous feel, or exhibit the soft spongy state which is well known to those who take the trouble to inquire into these matters, in such a case the treatment just described cannot be sufficient to prevent a permanent sealing up of the Eustachian tube. It is in these cases I have found iodine of the greatest possible service, when it has been employed early; and I feel convinced that if promptly exhibited internally, and applied externally, in recent cases, that many hundreds of persons will have the sense

of hearing preserved to them who would unquestionably fall martyrs were nature allowed to take her own course.

The iodine should be given with the hydriodate of potass, and should be combined with such other medicines as the state of the patient's health at the time indicates. I more frequently give it in combination with the compound decoction of sarsaparilla. The tonsils should, twice or thrice daily, be painted with the tincture of iodine, the strength of the tincture depending upon the general inaction of the part. Generally, three, four, or five weeks will elapse before the full effect of the iodine is produced.

I can speak more confidently of this remedy than of any other I have employed in diseases of the ear, and therefore hope that medical men will give it a fair trial in any such cases as may come under their notice. If deafness is to be relieved it must be done in a very early stage: and although patients are operated upon with the most solemn assurances of success, yet, with but few exceptions, do these operations ever succeed.

It is no uncommon thing, for deaf persons to come up from the country to undergo the *new* operation. The patient, generally very timid, is seated for the operation, and is surprised when it is finished, at having suffered little or no inconvenience: she is told she hears better, and from the fright she has laboured under her whole nervous system is excited, and she does in consequence really hear better for half an hour; but she will say, "it soon went off." Now this person imagines she has submitted to the operation, and is to be again subjected to it on the second or third day. This is repeated four or five times, when the patient, finding four or five guineas have disappeared, and that the hearing is not at all improved, takes her leave. Ask such a person if she has been sensible of air being forced into the tympanum; if she tell you no, and that she merely felt a gurgling noise in her throat, be assured no air has been forced through the Eustachian tube. If there be a stricture in this tube, the quantity of condensed air necessary to force for itself a passage is sufficient to produce the most alarming consequences.

It is from these unpleasant effects that the operation is now so often in-

completely performed. In many instances the air is not condensed, but is merely pumped in as required; and, in fact, for such a purpose, the simple action of blowing into the Eustachian tube from the mouth would be much more convenient and safe than any mechanical instrument.

The alarming symptoms which not unfrequently follow this operation are very often unknown to the operator; as the patient goes home, and in a few hours complains of giddiness: deep-seated pain in the head supervenes, the usual medical attendant is called in, and has found all his resources unable to subdue the inflammation.

If this operation be *ever* justifiable, it is yet manifestly improper if the patient have for any length of time suffered pain in the ear, the more especially if there have been chronic discharge; and yet we have been informed of such a case. The patient was operated upon on a Saturday, *and died on Wednesday*. There was no autopsy. Her symptoms, as described by a non-professional person, indicated suppuration of the brain.

It is very difficult to collect these unfortunate results, and if any member of the profession will send to the medical journals well-authenticated details of these unhappy cases, he will be conferring a real favour upon the profession, and which will be ultimately of essential service to the public.

We have never had an opportunity of examining the ear or brain of any person who has died soon after submitting to the air-douche, *but we believe the baneful effects may sometimes arise from the direct pressure of air upon the brain*; collapse being induced by the severe and sudden pressure to which the brain is exposed. In other cases, when a few days intervene between the operation and the death of the patient, inflammation has probably been induced in the labyrinth, which, extending along its lining membrane, is easily transmitted to the membranes of the brain; exactly in the same way as peritonitis would ensue were some cases of hydrocele to be improperly treated by the injection of stimulants, when the tunica vaginalis remains open. It is, doubtless, in this way that so many persons lose their lives, who have stimulants injected heedlessly into the ears; for there can be but little doubt

that the lining membrane of the labyrinth is a continuation of the dura mater and arachnoid; the labyrinthine portion being partially excluded, although not altogether shut out, from the splanchnic cavity, by the gradual deposition of ossific matter around the ducts of the vestibule and cochlea. Where inflammation of the internal ear has existed for any length of time, it is well known that a communication almost invariably takes place between the external and internal ear, by the absorption of the membranes which cover the fenestræ vestibuli et cochlea. Now it is when this communication really exists that these injections into the ear are doubly dangerous, as air might without any great power being used be forced into the cavity of the cranium. It must also be remembered, that even yet it is an undecided point whether or not these aqueducts are for the purpose of allowing the superabundant fluid of the labyrinth to escape into the cranium when undulating too powerfully; and although opposed to the opinion of Brugnone, Ribes, and Breschet, yet we have some modern and scientific anatomists who hold the opinion of Cotugno, which is certainly supported by the fact that these aqueducts are almost invariably present; which regularity would not be so constant were they merely for the transmission of blood-vessels. Now, supposing this fluid in the *natural* state to be so easily pressed into the cranium, merely by a somewhat louder sound than usual, only conceive, when these membranes have been removed by disease, and a direct communication exists between the external ear and the cavity of the cranium, *what must be the effect of the powerful air-press*. However, it is useless to speculate any longer upon this subject, our object having been to direct the attention of the profession to this dangerous operation—a danger which has, in some instances, *immediately* supervened, and has been the subject of investigation before her Majesty's coroners. And in other cases the same unhappy results have been as certainly, though more tardily, induced, without its having reached the ears of those who had performed this operation.

We would, therefore, endeavour to impress upon the profession the following inferences. That this operation of

injecting air into the Eustachian tube has been of *no* benefit, or it was of so extremely questionable a character as to leave an uncertainty in the minds of both the patient and operator;—that when this operation has been performed, it has often caused unpleasant, alarming, and dangerous symptoms, nay, even death itself—and, that in consequence of these dangerous effects, the operation is now so far *modified* as to be of little or no service in removing an obstruction in the Eustachian tube, or of benefiting those cases in which Deleau has so highly recommended it.

I am, sir,

Your obedient servant,

MEDICUS.

April 21, 1842.

## MEDICAL GAZETTE.

Friday, May 6, 1842.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

### CONTAGION AND QUARANTINE.

FROM a notice in the preceding number of the journal, our readers will have learned that at a recent meeting of the Medico-Chirurgical Society, the question of contagion and quarantine was brought forward, and elicited, as usual on all such occasions, the most singular diversities of opinion among those who took part in the discussion. It is certainly a remarkable circumstance, that in these days of pathological accuracy, when we boast, and justly boast, of our correctness in diagnosis, when we labour diligently and most successfully to develop the origin of diseased actions, in the several structures of the body, when a general accordance exists as to the effects of diseased actions, and a high importance is every where and by an universal assent attached to the study of morbid anatomy, there should be, at the same time, the most unaccountable diversities of opinion with

regard to the exciting causes of disease, and more especially of acute disease. The doctrine of contagion has proved a perfect apple of discord to the profession of physic. Whoever threw it first down, and this, as a matter of course, has been a fiercely-contested point, did more to embroil the medical profession, and has been the cause of more waste of pen, ink, and paper, than any controversialist from the days of Hippocrates downwards. We are about to shed a little more ink in the same great cause, but we do so without the smallest hope that what we are going to say will reconcile conflicting sentiments, or perceptibly lessen the annual amount of contributions to this *vezata questio*. We feel quite convinced that a hundred years hence the Gazettes and Lancets of those days will teem with papers on epidemic and non-contagious influence. The then existing supporters of contagion will be looked upon as men lagging behind in the march of intellectual improvement, as followers of an idle fantasy of the brain, incapable of proof; as well-meaning, but weak-minded and prejudiced pathologists. To all this we have quite made up our minds. Nevertheless, with our eyes wide open to the certain consequences of our labours, we still deem it advisable to add a few words more to the already innumerable effusions on the subject of contagion.

We marvel much at the tone and temper with which this controversy has been too generally conducted. A certain class of pathologists have imbibed a sort of instinctive horror at the notion of contagion. They have considered it as beneath the dignity of a scientific man to acknowledge such an influence. They have reasoned as if there were some confession of intellectual inferiority attached to the holding of such an opinion, and an emancipation from vulgar prejudices in the

avowal of anti-contagious notions. Such men would, we sincerely believe, experience a sense of shame in acknowledging the doctrine of infectious agency. That such feelings as these do exist widely throughout the world, more, perhaps, on the Continent than here, we are well convinced, and it is hard to account for such a circumstance. There seems nothing, *per se*, very revolting to common sense in the notion that the secretions of the body, in certain disorders, throw off emanations which, received into the lungs, and impregnating the blood of another person, should produce in him a like disease. Yet the great aim and object of certain parties has been to disavow such a principle, wherever, by any ingenuity, it was possible to adopt some other explanation,—never to admit such a doctrine except as a last resort in ætiological difficulty, and then to throw all possible discredit upon it.

The doctrine of a contagious and infectious quality is conceded to small-pox and to measles, by almost all pathologists, a large proportion of whom are ready to extend the same attributes to scarlet-fever and hooping-cough. Very many draw their line of demarcation here, and, like Falstaff with his ragged regiment, refuse to march a step further with the contagionists. A certain number, however, are content to include typhus fever, puerperal peritonitis, and the Egyptian plague, in the category of contagious maladies. From this point the non-contents have it pretty much their own way. The doctrine of a contagious quality inherent in the morbid secretions of cholera, of yellow fever, of erysipelas, and of influenza, makes some of them perfectly frantic, while the suggestion that perhaps the secretions may be similarly endowed in cases of phthisis pulmonalis, croup, or dysentery, is met with a look of ineffable contempt, mixed with pity.

It has always appeared to us that the doctrine of contagion and infection has been viewed by medical writers in too isolated a manner; that to arrive at correct conclusions on the subject, capable of any wide application in nature, we should commence with the simplest form of diseased secretion capable of communication from one individual to another of the same species (of which psora offers the best illustration), and trace the doctrine up to those more aggravated forms of disease, such as small-pox, where the whole mass of the body, the blood, the secretions and humours of the lungs; as well as of the skin, and perhaps the solids themselves, participate in this communicating or contagious quality; and that, not to individuals of their own kind only, but to the lower orders of animals; and by such *intensity* of infectious property convince the most sceptical of the truth of the doctrine. If we follow up this notion we shall have no difficulty in attaching the notion of a contagious quality not merely to the secretions of tinea capitis, of gonorrhœa, and of syphilis, but also to those of the jaws and of the malignant whitlow, to the purulent secretions of ophthalmic and certain other inflammations, to the vesicular secretions of erysipelas and varicella, and to the morbid products of the lungs, throat, and skin, in cases of hooping-cough, measles, and scarlet fever.

Entertaining these general impressions on the subject of contagion and infection, as applicable to various acute diseases where the secretions of the body are palpably affected, it cannot be a matter of surprise that we are strenuous supporters of the contagious nature of the Turkish plague. If ever a disease existed calculated *à priori* to throw off contagious emanations, this is it. It is a peracute form of fever of most malignant character, rapidly affecting the

nervous and circulating systems, and curiously altering the coagulable and other qualities of the blood. The best chance for the preservation of life under such a malady is afforded in the abundant discharge of buboes; presenting thus an analogy to the progress of variola as close as can reasonably be expected.

The objections to the notion of contagion, as inherent in the secretions of Turkish plague, are chiefly the following:—It is argued that the disease is obedient to the laws of epidemics—that it has its seasons of access, of culmination, and decline. This is undoubtedly most true, and most important with reference to practical measures; but epidemic influence is not opposed to, or incompatible with, a contagious or infectious quality of the fluids. The two circumstances coexist here, as they equally do in small-pox, measles, and scarlet fever. It is farther contended that medical men have exposed themselves freely and with impunity to the infected atmosphere of a plague hospital. True some have done so; others have been less fortunate. A thousand men go into action. All are alike exposed to the danger, but only a certain proportion fall victims to the shot and shells of the enemy.

The third argument of the anti-contagionist party is, that plague is not found to spread on the European Continent, though commercial intercourse with Egypt augments annually. Historical facts, however, are opposed to this statement. Plague spread at Marseilles in 1720, at Moscow in 1770, at Malta in 1813, in the Ionian Islands in 1818.

While we thus acknowledge our firm belief in the contagious qualities of the secretions that form in persons labouring under Turkish plague, and our equally strong conviction that the clothes, and bedding, and bed-furniture

of plague patients, may sometimes harbour such diseased secretions, and renew the disorder after a certain interval, either in the same or in a distant locality, we are perfectly ready to admit that the Quarantine laws, as now administered in the Mediterranean, are framed upon very mistaken views of the laws of pestilential contagion. The shortness of the incubative stage is not considered. The almost total impossibility that merchandize could be packed by persons in a condition calculated to throw off contagious emanations, seems utterly neglected. The practical inference deducible from the fact that the crew of a merchant ship remains free from disease for a period exceeding ten days, appears an element in the calculations of Quarantine law-givers wholly and most unaccountably left out of consideration.

We earnestly hope that the British Government will be induced to take some efficient steps towards the reform of the Quarantine regulations now in force throughout the Mediterranean. That the period of sanatory surveillance might be lessened in all cases, with perfect safety, we entertain not the smallest doubt. That the period should be the same in steam and sailing vessels appears a wanton trifling with valuable time.

No isolated measures for the reform of Quarantine laws, however, can be of any avail. To be effective, the subject must be taken up as a measure of international policy, and carried out with entire acquiescence on the part of all the chief Mediterranean powers. The British Government, however, might well initiate the proceeding, and congresses have been held on matters of less pressing necessity. We conclude, therefore, by heartily commending to Sir Robert Peel, when he has carried through his present scheme of commercial reform, the great question of Qua-

quarantine reform. We can confidently anticipate for him an abundant popularity from success in such an enterprise. A Gadibususque—from Gibraltar to Odessa, one universal cry of joy and gladness will arise, when Quarantine regulations are revised, useless restrictions abolished, and when the unhappy prisoner in the Lazaretto can console himself with the reflection, that reason and science have limited his duration to the shortest possible period compatible with national security.

#### DEATH OF SIR CHARLES BELL.

WE greatly regret to have to record the death of Sir Charles Bell, which took place suddenly on the morning of the 29th ult. at Hallow Park, near Worcester, the residence of Mrs. Holland, whom the deceased and Lady Bell were visiting on their way to Malvern.

Sir Charles had been subject to pains about the chest of a spasmodic nature, and latterly assuming the characters of angina pectoris. He had been very unwell at Manchester a short time before, and had suffered much from pains in the stomach during his visits at Hallow; but appeared quite as well as usual on the 28th, and had been out for a considerable time during the day. At night the pains again became severe, but no danger was apprehended until 8 o'clock on the morning of the 29th, when he became rather suddenly very quiet, and Lady Bell, greatly alarmed, sent for Dr. Carden, of Worcester, who, on his arrival, found him quite dead, with the appearance of life having been for some time extinct.

Sir Charles was 67 years of age, and, with the exception of the complaint which proved fatal, retained considerable vigour and activity. He was out sketching on the 28th, being particularly pleased with the village church, and some fine trees which are beside it; observing, that he should like to repose there when he was gone. On Monday last, being just four days after this sentiment had been expressed, his mortal remains were accordingly deposited beside the rustic graves which had attracted his notice, and so recently occupied his pencil.

[As the Number was passing the press, we received the following letter.]

*To the Editor of the Medical Gazette.*

SIR,

THROUGH the medium of a London paper I have this moment become acquainted with the great loss the medical profession has experienced by the unexpected death of Sir Charles Bell.

The pupils who have received his instructions knew him as a valuable teacher, the results of whose experience and extensive professional knowledge were eloquently and unreservedly communicated, in his lectures, for their instruction and guidance: few, as a friend, more warmly urged them to perseverance, and an honourable and liberal spirit, in the practice of their profession. With these feelings I propose that all who have been pupils of the late Sir Charles Bell should unite in erecting to his memory a monument, which might serve as a memorial of his professional and scientific learning, and a mark of gratitude for the excellent instruction they have received from him.—I remain, sir,

Your obedient servant,

E. M. R.

Gloucester, May 3d, 1842.

#### MEETING AT THE COLLEGE OF SURGEONS.

A meeting was held at the College of Surgeons on Wednesday, and was very fully attended: we should imagine that not less than 700 of the members were present, besides a great crowd of visitors. The chief circumstance of the evening was the lecture by Professor Owen upon the skeletons of the fossil animals, mylodon and glyptodon, recently added to the museum. He commenced by explaining the general principles on which John Hunter and Cuvier had applied the knowledge of comparative anatomy to the interpretation of the relations not only of existing, but of extinct species. Cuvier especially, working as he did in the most productive field of fossil remains presented in any of Europe, had illustrated this principle, which he termed that of the co-relation of the different organs of the same animal body to the general purposes of

its existence. The professor explained by several examples in which the examination of but a small portion of the skeleton had sufficed for the construction in anticipation of the whole body, and then proceeded to explain the history of the discovery of the megatherium. President Jefferson, by whom the remains were first particularly described, judging by the size and form of the ungual phalanx, had conceived them to belong to some huge species of lion; but Cuvier, to whom some casts of the bones were sent, felt convinced, by the form of the articulation of the phalanx with the next bone, which was not on the superior but on the anterior inferior part of the latter, that it must have belonged to a species in which the claw was employed for some more general and constant purpose than that of the mere seizing of the prey, for which it serves in the lion. He concluded, therefore, that it belonged to some species related to the sloths. This conclusion was at length confirmed in the drawings which Cuvier received of a nearly complete skeleton of the animal presented in the museum at Madrid: but still it was doubted whether the whole of that skeleton was formed of the bones of one animal, or whether the seemingly disproportionate head and pelvis were not derived from two distinct species. This doubt, however, was completely removed by the discovery of a certainly perfect skeleton of the new subgenus of megatheroid animals, the mylodon, of which he then demonstrated the most striking characters, pointing it out as an animal whose habit it must have been to feed on the leaves and soft parts of trees, by raising itself on its great hinder extremities, and pulling down the branches of trees with its strong forearm and its tongue. The latter organ might be believed to be at least four times as large as that of the giraffe, judging by the size of the apertures for the lingual and hypoglossal nerves. There was also a peculiar character in the arrangement of the phalanges of the anterior extremity; the internal being furnished with claws, while the two outer were of such a form as to render it certain that the animal must in progression have rested on their exterior surface; so as to combine in its one foot the ungulate and unguiculate characters upon which Linnæus had

based his division of two chief classes of mammalia. The glyptodon had, in relation to the megatherium, the great interest of proving to what animal the large portions of osseous carapace which had so often been found near the remains of the megatherium, belonged. They had been supposed, even by Cuvier, to belong to the megatherium itself; and he supposed it, in this respect, to resemble the armadillos. But portions of a foot, and of a lower jaw, brought from South America by Mr. Darwin, had rendered it certain that some gigantic species of the armadillo tribe existed in the neighbourhood of the megatheria; and this had at length been proved by the discovery of the glyptodon, of which the College had purchased the carapace; the bones of the greater part of the skeleton having been so injured in the exhumation that they could not be transferred to this country. The Professor concluded by offering some striking observations on the characters of the fossils found in England, and on the peculiarities of the soil and climate which they proved to have been natural to this country in the periods previous to the existence of man.

After the lecture the company adjourned to the Council Room, where tea and coffee were provided, and to the museum, which was brilliantly lighted for the occasion\*.

## ROYAL MEDICAL & CHIRURGICAL SOCIETY.

April 26, 1842.

DR. MERRIMAN IN THE CHAIR.

### *A Case of Dislocation of the Knee, with Observations.* By HOLMES COOTE, M.R.C.S.

THE object of the author in the relation of the case here presented, and in the observations which follow it, is to insist upon the practical inference, that in dislocation of the tibia forwards (or of the femur backwards) the injury to the ligaments, and other soft parts about the knee-joint, is not necessarily such as to render the recovery of the limb in a perfectly useful state a forlorn hope, as it has been represented by writers of high authority, some of whom have almost regarded

\* We presume that it was the announcement of this meeting which led to the idea (which proves to be erroneous) that conversazioni were to be given in Lincoln's Inn Fields like those formerly held at Pall Mall.

amputation as *prima facie* necessary to save the life of the patient.

Boyer, among others, observes that "complete dislocations are rare, because the surface of the condyles of the femur is of so great extent, that, necessarily, ligaments, tendons, and all other soft parts, would be enormously torn; a circumstance that could not happen, unless the power producing the accident acted with extreme force," &c. Delpech speaks of these accidents in the same tone, as very serious, in the degree of laceration which must attend them, but is disposed to recommend caution in adopting the conclusion of some other writers, that amputation of the limb is necessary.

In the case related by the author, the reduction was easily effected, and the injury of the soft parts must have been slight, as the patient was on his legs, and able to run, in sixteen days. He enters at some length into the anatomical examination of the ligaments of the joint, for the purpose of showing that dislocation may take place without any material laceration of them. Some interesting remarks follow on the time required for the re-union of lacerated tendons and ligaments, partly founded on observations of the progress of cases in which the former have been divided on account of distortions; and the paper concludes with some considerations on the treatment applicable to distortions of the knee.

*A Case of Fungus Hæmatodes.* By S. W. J. MERRIMAN, M.D. Physician to the Westminster General Dispensary, Gerrard Street, Soho.

A delicate boy, seven years old, suffered for some months from debility, and anomalous rheumatic pains. Two very painful tumors were then observed, one arising from the occiput, the other from the forehead: constant pressure on these tumors tended to diminish the pains: the tumors grew rapidly in size, spreading in various directions, by which the left eye was nearly thrust out of the socket; œdema supervened in the lower extremities, and death ensued in about ten weeks from the appearance of the tumors. The post-mortem examination showed these to be of a medullary nature: arising from the diploë, the internal table of the skull was scarcely at all affected, but the external was thickened, and covered, wherever the tumors had spread, with bony spiculae shooting up into the morbid growth. Some of the ribs were also affected with the same disease, and many axillary, lumbar, and inguinal glands were converted into a similar bloody brain-like substance, but, generally speaking, the viscera were healthy. In conclusion, the author notices the boy's mother, who has nearly lost the use of her wrist and

knee-joints by a species of chronic rheumatism, acting in a peculiar manner, and producing no distortion.

*A Case of Congenital Cataract, where sight was acquired by couching at the age of twenty-three years.* By R. A. STAFFORD, Surgeon to the St. Marylebone Infirmary.

The disease in the case here related was of the capsulo-lenticular variety, and the operation was performed by depression, the lens and capsule being carried downwards and backwards into the vitreous humour out of the field of vision. The patient's recovery proceeded very satisfactorily, and in the course of it phenomena were exhibited differing in some material respects from those described as having occurred in the cases narrated by Mr. Cheselden and Mr. Ware, in the Transactions of the Royal Society.

Among these phenomena, all of which are minutely detailed by the author, the most remarkable was the power gained by the patient, a very short time after the operation, of accurately estimating distance. The author believes that his patient was more advanced in age at the time of the operation than any other upon whom the operation for congenital cataract had previously been performed with success. Mr. Cheselden's patient was 13, and Mr. Ware's only 7.

## CIRCULATION IN THE BRAIN\*.

*To the Editor of the Medical Gazette.*

SIR,

MR. BELL denies that the brain feels the pressure of the atmosphere directly or indirectly. It will not be difficult to prove to the satisfaction of Mr. Bell that the brain *does* feel this pressure, and that he might have been spared his anxiety to stop the progress of an erroneous doctrine.

If the skull were a *complete* case of bone, without the least perforation for the transmission of blood-vessels or nerves, then, indeed, it might be truly said that the brain is exempt from the pressure of the atmosphere; but let there be the smallest foramen transmitting the smallest capillary to the brain, then most assuredly the minute thread of blood to which it affords a passage will as certainly convey the pressure of the atmosphere to the whole mass of the brain, as the water in the small cylinder of an hydraulic press conveys the power acting upon the piston to every part of the reservoir.

But there is more than a capillary vessel:

\* In my last communication, p. 110, column 2, line 15, for "Mr. Bush" read "Mr. Rush;" line 22, for "form" read "force;" lines 34 and 35, for "whenever" read "wherever."

there are large arteries and veins which form a communication between the interior and exterior of the cranium : upon these the atmosphere undeniably presses *before* they reach the brain : it will be easy to show that they feel the full force of this pressure *after*. Confined fluids transmit pressure to any amount to any distance ; the columns of blood therefore which receive the atmospheric pressure without the skull convey it to the minutest ramifications of the vessels within ; and more, the coats of these vessels being elastic, transmit this pressure to the substance of the brain, which again transmits it to the inner surface of the cranium, which being unyielding will not transmit it any further.

The skull, its contents, and connected vessels, are in the position of a long-necked globular vessel, filled with water, and any substance of the consistence of brain, and turned upside down ; the narrow neck corresponding to a blood-vessel, and the globular part to the skull and brain. The operation of atmospheric pressure can no more be denied in one case than in the other.

Mr. Bell's error seems to arise from an impression that atmospheric pressure on the brain implies direct pressure upon its surface, acting from the periphery towards the mass ; whereas the brain is so circumstanced that the direction of the pressure is from the outlets of the skull, giving passage to the blood-vessels and nerves towards every part of the surface of the brain in contact with the dura mater.

Dr. Kellie's experiments prove that blood-letting does not diminish the quantity of blood in the brain under ordinary circumstances ; but they do not prove that this organ is free from the influence of atmospheric pressure : indeed, it is this influence acting upon the vessels entering the cranium which prevents the diminution of blood within it : abstract this influence, by placing a decapitated head *in vacuo* in a favourable position, and the gravitating tendency of the brain and of its blood will come into operation ; the brain will sink, and the fluid escape : overcome it by a shock, in the way described in my first communication, we have the same result ; counteract this influence in one direction by establishing it in another, that is, by removing a portion of the skull by trepan, again we have the same result ; provided, at the same time, we diminish the tension of the vessels and the form of the heart by blood-letting. It is impossible to diminish the quantity of blood in the brain by blood-letting alone, as long as vessels entering it receive the unimpeded influence of atmospheric pressure. It thus appears that Mr. Bell and I draw opposite conclusions from Dr. Kellie's

experiments. Would it have been "preposterous" in Mr. Bell to have forsaken assertion, and pointed out *how* the experiments alluded to prove that the effect of atmospheric pressure is not felt within the cranium ?

Your correspondent allows that the removal of a portion of the skull admits the pressure of the atmosphere upon the brain. What difference is there, as far as this pressure is concerned, between the artificial removal of a portion of the bone and the natural absence of it for the passage of vessels and nerves ?

The experiment of removing a portion of the skull in order to diminish the quantity of blood in the brain, is just the same as making an opening at one end of an egg to enable us to extract the contents from an opening at the other end. The two cases are analogous ; the atmospheric pressure acting upon the vessels entering the cranium, maintains a steady quantity of blood within it, in the same manner as this pressure retains the contents of an egg *in situ* when an opening is made at one end only. The egg may be laboriously sucked, but little or no progress will be made in emptying it, unless a counter-opening is made at the other end to establish the equilibrium of atmospheric pressure : this is a fact familiar, in these later times, to every grandchild.

I do not see how I have *made* Dr. Holland's statement support my views, except by legitimate inference. That author states a fact, viz. that aeronauts do not suffer from vertigo, while it is well known that mountain pedestrians do, when they have reached a high elevation. To ascertain the reason of this, we must inquire into the different circumstances attending each case. We find that the pedestrian is liable to bodily fatigue, and to shocks arising from the acts of walking or leaping ; while the aeronaut is exempt from both. We may infer, therefore, that the cerebral symptoms are connected either with bodily fatigue or with shocks. Dr. Holland adopts the former inference ; my views lead me to adopt the latter. My suggesting the substitution of the word "shocks" for "bodily fatigue" clearly indicated that *my* opinion would be expressed, and not Dr. Holland's. In short, this author supplied a fact from which I drew an inference. In what consists the "novelty" of the above mode of reasoning I am at a loss to discover.

When Mr. Bell says that his note was penned in the spirit of kindness, I give him full credit ; it was my own impression when I read it, and I expressed as much to my friends. I hope I have displayed no marks of asperity or acrimony in my last or present communication ; for I am sure I have felt none. Truth is my only object, and I can-

not find fault with the best means of attaining it—discussion.—I am, sir,

Your obedient servant,  
THOMAS HAWORTH.

Bolton, May 2d, 1842.

### ARRESTING OF HÆMORRHAGE.

*To the Editor of the Medical Gazette.*

SIR,

HAVING read in the LONDON MEDICAL GAZETTE of the 1st of April, a case of serious and alarming hæmorrhage after the extraction of a tooth, which occurred in the practice of Mr. Davenport, of Eltham, Kent, and having experienced the feelings of anxiety attending such an alarming event, in several similar cases—one of which you were kind enough to insert in your journal, that terminated fatally—and as Mr. Davenport requests to be informed of any remedy that may have succeeded in such a case, I take the liberty of requesting your inserting one that a gentleman, a surgeon, kindly sent to me, after having read the case I allude to in the LONDON MEDICAL GAZETTE, and which he found effectual after he had tried every thing that could be thought of. He says, "upon the spur of the moment I filled the bleeding cavity with 'plaster of Paris,' which effectually checked the hæmorrhage in a very short time." When it is considered how rapidly plaster of Paris absorbs moisture, "it must soon become coated with the coagulating principle of the blood, which is left in a manner dry upon the plaster," and from the plastical nature of plaster of Paris when moistened, it may be so completely pressed into every little depression of the alveolus, and consolidating there, be the most perfect plug that could be applied, being held down for a few seconds by the finger until hardened. Should you think this, I really think, valuable hint worthy of a place in your Gazette, it will be an additional favour conferred upon

Your obedient servant,  
W. A. ROBERTS.  
Surgeon and Dentist.

11, Duke Street, Edinburgh, April 22, 1842.

*To the Editor of the Medical Gazette.*

SIR,

CASES of alarming hæmorrhage after the extraction of teeth having been recently published in your Gazette, and the *London and Edinburgh Medical Journal*, and as one of your correspondents, Mr. Davenport, wishes to be informed of some remedy that will suppress similar bleedings, I am in-

duced to inform him, through your valuable pages, that the most certain and easy remedy I have ever found succeed in several cases which have come under my notice, has been to replace the tooth (whether single-rooted, bicuspid, or having three or more fangs) which, in a few days, becomes firm and often serviceable. The superiority of this practice over every other is evident from the impossibility of fitting any substance to the cavity so accurately as the tooth which had been previously extracted, and which, unlike cork, sponge, lint, &c. need not be removed. Mr. Davenport was surprised to find the hæmorrhage persistent, although the "cavity was filled with a coagulum nearly as hard as liver." About three years since I saw a young man of hæmorrhagic idiosyncrasy, who had accidentally scratched his tongue, and bleeding, to a most alarming extent, supervened. When I first saw him, his tongue was thickly covered with a large, firm, dark, and foetid coagulum, the smallest puncture of which became a fresh bleeding point. The hæmorrhage was finally stopped with Lycoperdon and Tinct. Benz. Co.

I am, sir,  
Your obedient servant,  
JOHN MOYLE.

Chacewater, Cornwall,  
May 2d, 1842.

### ATTENDANCE ON THE POOR.

*To the Editor of the Medical Gazette.*

SIR,

ON reading the Schedule issued by the Poor-Law Commissioners, and published in your last number, respecting the qualifications of medical officers, Art. 3, whilst I cannot but highly approve of the double qualification therein required, yet, unless I mistake the existing law very much, I am persuaded they have no power to enforce such regulations without a new legislative enactment, because, according to the 4th and 5th Will. IV., cap. 76, "every person duly licensed to practise as a medical man" is eligible to the appointment of Union Medical Officer. But the present regulation goes to repeal this part of the Act, and to introduce a qualification which the law does not recognize—a degree in medicine from an English university, or from the Royal College of Physicians in London, and a diploma from the Royal College of Surgeons. Now I would contend that such a qualification does not come within the meaning of the Act; a physician or surgeon not being, in the eye of the law, "a person duly licensed to practise as a medical man:" indeed, I believe it has been decided in several cases that neither

the surgeon or physician can act as an apothecary, unless he also possesses the requisite license.

Should I be wrong in my views on the subject, I shall be greatly obliged by some of the readers of your valuable periodical setting me right.—I am, sir,

Your obedient servant,  
M. D.

April 30, 1842.

## ROYAL COLLEGE OF SURGEONS IN LONDON.

*To the Editor of the Medical Gazette.*

SIR,

I AM desired by the President to request you will give a place in your journal to the following notice, which may be interesting to many members of the profession.—I am, sir,

Your obedient servant,  
EDMUND BELFOUR, Sec.

April 23, 1842.

THE catalogue of the specimens of urinary calculi in the museum of the College, about 600 in number, illustrated by twelve engravings, plain or coloured as may be desired, is now in the press, and will be delivered to members of the College at the cost of the paper and letter-press only; no charge being made for the plates unless coloured.

Members desirous of possessing a copy are requested to send their names to the secretary, at the College, on or before the 10th of May next, in order that the number of copies necessary to be printed off may be in some measure ascertained.

The first volume of the Transactions of the College will shortly be published, and will be sold at cost price to such members as shall transmit their names to the secretary on or before the 10th of May next.

[We readily comply with the request of inserting these notices, which, however, had already appeared on the wrapper.—E. G.]

## STUDY OF MENTAL DISEASES.

IN order to place the question at issue in a proper light, it appears useful previously to examine into the actual state of medical education generally pursued in this country, especially respecting the study of mental diseases; because, if the means for acquiring information, on such an important malady as insanity, be as defective as I believe them to be actually, the necessity for some alteration, in the present system, becomes consequently more imperative. Undoubtedly, throughout the whole range of medical science, it must be acknowledged

that nothing can well be more limited than the means of obtaining practical knowledge, which the medical profession at present possess, in this department of study; notwithstanding its obvious importance to the community. Since not only are the opportunities for investigating mental diseases of a very partial description, but the subject of insanity does not even form an essential part of the stipulated courses of lectures, required by the various licensing medical corporations from the candidates for their diplomas. Indeed, excepting by the teachers of medical jurisprudence, mental diseases are seldom alluded to, much less properly investigated; and even when the subject of insanity is actually noticed in these lectures the inquiry is only of a secondary or legal description, and neither embraces sufficiently the pathology of this extensive class of diseases, nor the curative treatment which the physician ought to pursue. In fact, the investigation of diseases of the mind, their nature, and the remedies best adapted for their cure, if not wholly neglected, are very partially investigated, by the general medical student. And this serious defect in medical education will continue to prevail, until the different medical colleges require from the aspirants for their much coveted honours, not only previous attendance upon lectures on insanity, but also clinical instruction at an hospital where lunatic patients are admitted; whose doors ought therefore to be freely opened, under proper regulations, to those students who may be anxious to obtain information. In consequence of the difficulties at present impeding the diffusion of knowledge on this important subject, and as it does not constitute an essential part of medical education, the study of mental diseases at the present day is too much neglected, excepting by a very limited number of medical practitioners who confine themselves to that department of their profession, and therefore do not usually practise in any other class of diseases. This division of labour, as it may be called, is found to be advantageous in the metropolis, and in large towns; but any restriction regarding the knowledge of insanity is by no means useful to the public generally, and acts injuriously on the great majority of medical practitioners in the country, who should be as well versed in the treatment of mental diseases as in those of the chest, or of any other part of the human frame. Many are undoubtedly quite competent for the treatment of mania; but my wish is, to make that knowledge universal in the profession. But although impressed with the importance of the subject, should any pupil, during the usual period of his preparatory studies, wish to obtain experience and information on insanity, the path to knowledge is so beset with difficulties, that

notwithstanding all the zeal he might otherwise have, the student would find it almost impossible to attain his object, unless through personal favour, or at a very great expense; neither of which alternatives are desirable means for acquiring knowledge, in a liberal profession.

Considering doubt can reasonably exist regarding the advantages which would ensue to medical men, and to society at large, by improving the present defective state of medical education, in relation to insanity, the only question therefore now requiring investigation is the best way for effecting the requisite alterations. On this head, the same method which is pursued in the study of other branches of medical science apply with equal force to this particular class of diseases; namely, the student must acquire practical knowledge and experience in mania through the medium of lectures; and also learn properly to apply the doctrines he has been taught, by attendance at the bedside of patients affected with mental diseases; as, in that way, the future practitioner can alone properly qualify himself for the arduous duties he must afterwards undertake. To attempt effecting that object, by any other mode, would only lead to disappointment, tend to perpetuate ignorance, and prevent real improvement. Reading will, no doubt, considerably assist the student in investigating affections of the mind; but that method of study will not be sufficient, for without actual observation of this disease, when variously affecting the human constitution, any knowledge otherwise obtained is neither so available in practice, nor will prove so useful to the patient, as experience acquired from personal attendance upon insane patients; especially when that mode of study is pursued under the guidance of experienced teachers, and those accustomed to instruct their junior brethren, in the wards of an hospital. From these remarks it follows, that the most useful method to adopt, for improving the knowledge of medical men in mental diseases, would be, in the first place, to open the doors of our great public hospitals for the reception of the insane, as, for instances St Luke's, Hanwell, and Bethlem, to medical students under proper regulations, should they feel desirous of investigating insanity in the extensive fields for study which these institutions contain. It would likewise prove of much use, if the medical corporations, prior to granting their diploma, were to exact attendance at such hospitals for a limited period, and also attendance at lectures on the nature, pathology, and curative treatment proper for that class of maladies. However, if this recommendation should be adopted, the expense entailed upon the medical student ought not to be

considerable, lest the object proposed might thereby be materially interfered with, or even perhaps defeated.

Bethlem Hospital, from being pre-eminent for its excellent arrangements, and having extensive wards, containing generally from 310 to 340 patients, is an institution admirably adapted for the purpose of obtaining instruction; and being principally intended for the reception of insane patients, who are considered of a curable description, although not exclusively so, since there are likewise incurables and criminal lunatics; that hospital, therefore, possesses many advantages for the purposes of study, over other establishments, in which every description of patients, whether curable or otherwise, are received. The attendance of medical students, in the wards of such an extensive hospital as Bethlem, where a great variety of insane patients are constantly under treatment, and from five to six new patients are admitted every week, would therefore be most useful; particularly if compared with other lunatic asylums, containing paralytic, epileptic and incurable lunatics or idiots, almost indiscriminately. Of course cases of that melancholy description are by no means unimportant to the medical student, and ought likewise to be investigated by the diligent inquirer, in order to alleviate if possible their sufferings, however hopeless any prospect of their cure may appear. But as the majority of medical practitioners are more likely, in the course of their professional practice, to be called upon to treat the less severe, and curable varieties of insanity, than cases of a chronic description, knowledge of the ordinary forms of recent diseases, is, therefore, most important: and considering it will be admitted that few institutions are better adapted for studying mania in every variety than Bethlem Hospital, such reasoning applies with peculiar force to that institution. Besides these advantages, it ought to be recollected, that the medical officers of the establishment, being men of great experience and acquirements in their particular departments, and as there is a resident apothecary in constant attendance upon the patients, as also a matron, who, to great kindness of manner and firmness of character, possesses other qualities eminently adapted for the superintendant of female lunatics, with functionaries for each department,—nothing is really wanting at Bethlem Hospital to make the establishment in every way useful to the public, but a more free admission of medical students to the wards of the hospital, whereby the ultimate benefits accruing to society, may be extensively disseminated.

Objections may, perhaps, be taken by the governors, lest the excitement and noise

occasioned by the attendance of pupils in the wards of Bethlem, unlike any other lunatic asylum, might produce injurious effects upon the patients, especially upon the females.

Undoubtedly indiscriminate admission, or permitting crowds of visitors at irregular hours, would not be judicious; and, even in some instances, might be attended by injurious consequences to individual patients, when affected by mental alienation; but in the great majority of cases, no serious injury could arise from the physicians being accompanied, during their professional visits, by a few medical pupils; indeed, the danger appears to my mind to be very slight, if not imaginary\*.

### ULCER OF THE STOMACH.

#### CORONARY ARTERY OPENED.

MR. SMITH laid before the Society an example of ulceration of the stomach, taken from the body of a man, set. 79, who had been for many years before his death subject to biliary derangement, and symptoms of aggravated dyspepsia: three weeks before his death he was attacked by severe vomiting, and considerable quantities of blood were ejected from the stomach; he could not retain in the stomach either solids or fluids; the deglutition of fluids, in particular, was followed by severe vomiting; the alvine discharges were also mixed with blood; he also suffered from an enlargement of the prostate gland.

*Autopsia.*—A circular ulcer, about the size of a shilling, was found near the pyloric end of the lesser curvature of the stomach; the ulcerative process had opened the coronary artery; the surface of the ulcer was foul, and of a green colour, and the stomach very vascular; the middle lobe of the prostate gland was greatly enlarged, and formed an irregular tumor, projecting into the bladder; the bladder itself was distended, so as to be capable of containing nearly three quarts of fluid; its parietes were remarkably thin, but the muscular fibres unusually distinct, giving the interior of the organ a reticulated appearance; between these packets of muscular fibres the walls of the bladder were diaphanous; the mucous membrane presented the anatomical characters of chronic cystitis.—*Dublin Journal of Medical Science.*

INTRODUCTORY LECTURE  
TO THE  
COURSE ON MIDWIFERY.

*Delivered at London University College,  
May 3, 1842,*

BY DR. EDW. W. MURPHY,  
Professor of Midwifery.

IN commencing a course of lectures, it has become a general, I might almost say an universal, practice to preface them with some observations introductory to the subject about to be taught; and whether it be its history, its improvement, or the means of studying it with most advantage, the teacher will endeavour to bring forward such matter as may appear to him best calculated to encourage the student, and to smooth the difficulties of his pursuit.

In compliance, then, with custom, if I had no better motive, I should devote the present lecture to such a purpose; but when I reflect upon the honour that has fallen upon me in being entrusted with the obstetric education of the pupils of this College, and, a stranger to you, find myself called upon at once to enter upon those duties which I have volunteered to undertake, it becomes imperative upon me to give you some general outline of my views as to the nature of the subject you are about to study, as well as the method in which you might pursue it with most advantage to yourselves. Had I not this very powerful reason, I confess that the subject itself would supply me with a very strong argument against being silent upon its interests, because I believe that I am not incorrect in saying that of all medical sciences which have been objects of scientific research or of practical inquiry, none has met with a more chilling indifference, none has been treated with more unmerited contempt, than midwifery. Until very lately, expelled from your medical Colleges—at least, I believe, made a disqualifi-

754.—XXX.

cation for their honours, and for a long time looked upon as a pursuit unworthy the energetic intellect of man—it had been suffered to sink in the obscurity of an anile occupation, receiving scarcely a higher estimation than the spindle and the distaff. If this had been a justifiable prejudice—if the profession you are about to enter had been deservedly placed in a lower rank—if it had not suffered rather from its misfortunes than its faults—considered contemptible because practised by those who could not command respect—unintellectual and unscientific because it numbered, even amongst its successful followers, those who gave little proof of intellect and less of science—if midwifery had not been despised because it was misunderstood—I should not think it necessary to occupy your time with feeble efforts to magnify my subject; but when I feel convinced that a cloud of unsubstantial prejudices have obscured its real nature, it is my duty, and shall be my object, to prove to you that, whether as a subject of scientific investigation or of practical pursuit, whether as containing valuable facts to assist and encourage the researches of the physiologist, or as embracing points of practice which require all the discernment and decision of the accomplished physician, midwifery holds a place in no way inferior to those branches of our profession which have been looked upon with more favour, and have received a larger share of professional patronage.

Two circumstances have contributed more than any other to depreciate the study of midwifery. One is, the facility with which it may be practised. It being, in the great majority of instances, the observation of a natural process, in which we have only the negative duty of avoiding interference unless some unexpected interruption may take place, there are few occasions in which the knowledge and experience of the practitioner is put to the test: having, therefore, this security from

T

exposure, it is not surprising that the ignorant, who were never remarkable for diffidence, should gladly adopt it, and profit by a practice which they could not improve. But, gentlemen, let not this deceive you; in the practice of midwifery there is one fact which cannot be too strongly impressed upon your minds, and which should teach you caution, lest those apparent facilities should beget an indolence of which you might one day repent. It is quite true that, in general, you will not have difficulties to contend with; but those cases in which they do occur, or where danger presents itself, generally give little time for consideration: if your minds are not prepared with the requisite information, and your judgments matured by patient observation, so as to act on the instant with promptitude and decision; you are given no time to seek for information, you will become embarrassed, and incapable of undertaking the principal duty you were called upon to perform. In failing to secure the safety of your patient, need I tell you the painful situation, the unenviable feelings, of the practitioner who, through his ignorance, has snapped asunder the dearest tie of society—who has converted a house of joy and anticipated congratulation, where, perhaps, a happy result was confidently promised, into a house of mourning, in which a desolate husband and an orphan family have to pay the penalty of his presumption and neglect.

Another disadvantage under which, it appears to me, that midwifery is placed, is the want of a distinct obstetric board or centre of education. If it should be that your friend is afflicted with fever, that a sister is threatened with consumption, or that any of those who are dear to you is attacked with some one of "the thousand ills that flesh is heir to;" you have a College devoted to the education of the physician; one which requires from him not alone a knowledge of internal diseases and their treatment, but such testimony of a liberal education as will insure the capability of improving the profession he has studied, and of bringing to the observation of such maladies a previously-cultivated and enlightened understanding. If you become the subjects of some one of the various and sometimes most serious accidents that are of daily occurrence, or are liable to any of those external and often disgusting diseases that render life miserable, you have also a College to superintend the instruction of the surgeon, and to secure to you a well-educated practitioner. These Colleges are proofs that such matters are considered of too serious an importance to the public welfare to entrust to every casual or ignorant pretender. But if the question be the safety of a wife in her hour of trial, the health of her infant, or the relief of those diseases which depend

upon the derangement of a natural function, not a few of which are the result of ignorant mismanagement—if it be the determining any of those important medico-legal questions upon which so many vital consequences hang, as the existence of pregnancy, its duration, &c. &c., the fact of infanticide—you have no board exclusively devoted to superintend the education of practitioners in this important branch of professional knowledge. The student in midwifery may be a physician or a surgeon, may be a midwife or a quack; any thing, in fact, but an obstetrician.

Is it surprising, therefore, that midwifery has been held in humble estimation, and that any character it has been able to acquire is alone attributable to the talent, industry, and zeal of some of those ornaments of our profession whom accident has led to the study of it? I do not mean to inquire into the causes which have led to this, nor to depreciate the exertions of those medical bodies who have, with laudable industry, endeavoured, as far as in them lay, to remedy the evil; it is sufficient to know that while other branches of medical science have a head and independent existence, midwifery has none, and depends alone for its security upon the strength and flourishing condition of that body round which it can most intimately entwine itself; and therefore this fact may be justly assigned as one of the causes why its importance has not been appreciated as its merits. I trust the time will not be far distant when the efforts which are now being made in the different centres of medical education in its favour, will be crowned with success: and as they have made it imperative on the student to attend courses of lectures on the subject, and to give proofs of a certain amount of practical experience, so they will hereafter give him the advantage of a diploma distinctly testifying to the knowledge he has acquired, which would be more satisfactory and honourable to him if it were the result of an examination conducted by a board composed of men distinguished as the especial cultivators of this branch of our profession.

I have stated to you, gentlemen, that, whether as a subject of physiological inquiry or of practical observation, midwifery is in no way inferior to the other branches of medical science. I shall endeavour to illustrate, and I trust shall satisfactorily prove, my assertion.

If I were to ask you what series of observations occupy, in the present day, the greatest attention, and give the deepest interest to physiology, I am sure you would point to embryology—to those microscopic researches which are directed to unveil the mysteries of our earliest existence: if so, then surely you will not deny to midwifery the honour of a branch of medical

science so peculiarly its own, or say that its study is unimportant to the accoucheur. It is this fallacy that has led to the most absurd mistakes, and has retarded, if not altogether prevented, another subject of inquiry of almost equal interest—the pathology of the ovum. When abortion takes place, the ovum may be blighted, the membranes diseased, and various morbid phenomena presented to the accoucheur, which he either passes by unnoticed, or mistakes for a healthy condition, simply because he knows little of the healthy ovum. Hence I have known an ovum, blighted in the second week, but retained in the uterus for six weeks or two months, presented as a specimen of the foetus two months old. I have known a simple clot of blood, retained for some time in the uterus, so that the serum, in place of escaping, was collected in the centre, and was surrounded by a strong cyst of fibrine, produced as an abortion, in which the foetus was absorbed. These absurdities could not arise with you who have been already educated so efficiently in this branch of obstetric knowledge. I only ask you to admit with me that it is important as a branch of your profession, and is a subject of intense interest to the physiological inquirer.

Permit me now to give you another illustration of the advantages which the well-educated obstetrician is to the physiologist, in being able to appreciate the value of facts which bear upon some of his most interesting investigations. It will be your province to aid in bringing into a new existence the perfectly-formed embryo; you have the best opportunity of witnessing any deviation from its ordinary appearances; under your notice must, therefore, fall those exceptions to its normal development to which we apply the term "monster," or "monstrosity." These strange conformations have always attracted attention; but, as their name implies, have been objects only of disgust or superstitious dread. Within the last few years, however, they have been brought within the limits of scientific research, and are found, when more closely examined, to present as attractive a subject of enquiry, and to illustrate questions of as high an interest, as any that may be met with in the study of nature.

The endless varieties of form, and the multiplied combinations of creative intelligence, have always been the theme, as they have been the admiration, of science: and it has been the proudest effort of philosophy to trace amid this maze of ever-varying results the simple mechanism which moves the whole. Still the most determined laws have had the most embarrassing exceptions; but it is remarkable that a stricter analysis has proved that these very exceptions, when more accurately examined, have become the strongest evidences in support of the law. What has already been determined in other

sciences, the physiologist has attempted to establish in the animal economy, and has sought to prove that these odd irregularities in shape, these repulsive blots upon our nature, are but so many proofs of the laws which regulate our organization.

He has endeavoured to show that these remarkable exceptions to our natural conformation but illustrate the uniformity of the general plan; and that the very extravagance of forms, which seem to indicate Nature in her wildest whim, only establish the unity of her design, and are so many illustrations to teach us the successive processes by which the perfection of our being is attained.

One of those laws may be stated to be, "that in the development of the embryo the growth of different parts is not simultaneous; that an order of succession is observed, by which structure follows upon structure, organ upon organ; and that what is true of an organ, or of the embryo as a whole, is equally true of the several parts of which the organ may consist." The perfection of art has given to us, in the microscope, an unexpected aid in revealing to us the certainty of this law: it has enabled us to perceive the almost ultimate element of our being, and to trace the formation of the several tissues and organs as they successively appear. But the same conclusion might be inferred from monsters: the elementary membranes, which form the intestine, the skin, and the spinal canal, are found in all monsters. In the cerebro-spinal system, those parts first formed, the spinal marrow, medulla oblongata, optic tubercles or corpora quadrigemina, are generally found, though the remainder be deficient. If, in this order of development, we may assume that some disturbing cause gives rise to an undue activity in the growth of a part which precedes, or if there be an arrest in that which is to follow, the necessary effect will be, that the organ earliest formed will impede, if not altogether prevent, the completion of that which is later; or the arrested organ will leave a vacuum for the former to fill up. For example, if we take the face, we find the eye to be one of the earliest organs formed: if the development of the nasal apparatus be arrested, which succeeds it, the eyes converge, coalesce, become apparently single, and thus are produced that singular class of monsters called "cyclops." Again, in the abdomen the intestines are earliest formed, even before the septum which is the boundary between the thoracic and abdominal cavities: hence the intestines are always found, though the diaphragm may be absent, or imperfectly formed; and sometimes, in the latter case, the intestines will occupy the thorax, and thus arrest the growth of the lung, which is later in its formation.

Other examples might be quoted to prove that certain monsters become only so many illustrations of the law of successive development. An attempt has been made to go even farther than is, but which has failed only because the facts are too limited to authorize so general a conclusion. It being established that the germ of the embryo did not contain within it all the parts and organs which afterwards were successively brought into view, but that, from the simplest formation, it gradually attained the most complex, and also it being found that, in the different stages of foetal growth, certain resemblances could be traced to the permanent type of the lower animals, it was a question sought to be proved whether the foetus did not pass through the perfect form of the different orders of the animal kingdom, beginning with the lowest, and so proceeded through each class until it attained the highest. Many strong analogies favoured this opinion: for instance, the simplest form of animal life is found to be a mere vesicle containing fluid, as in the hydatid (a cyst containing other cysts, of which it is the parent): such also is the first germ of our being; a microscopic parasite; a compound vesicle which, on its entrance into the uterus, is covered with villi that become equally a means of attachment and support: if the further progress of its development be arrested at this stage, the vesicle continues to increase until the uterus throws it off as imperfect, when it appears as an enlarged cyst, with scarcely a trace of the future foetus existing in it.

As the foetus advances in its growth, new analogies to the different orders of the animal kingdom present themselves, and those organs which it has in common with animals lower in the scale, always precede in their appearance, and attain perfection sooner than, those of the higher class. Thus the scarcely convoluted intestinal tube, single circulation, and ganglionic nervous system of the invertebrate animals, are first formed; while those organs for the more elaborate secretions—the double circulation, and the sensorial nervous centres—are later in attaining perfection. This may be illustrated from certain monsters: we know of none in which the intestinal canal is absent, but there are those that have only the simple intestine; there are none which do not possess a circulating system, but there are examples in which the heart is altogether absent; the ganglionic series may always be found, but the cerebro-spinal axis is sometimes wanting. The order of precedence is thus proved; because arrests of development always affect those parts latest in their completion.

If from the invertebrate you pass to the vertebrate animals, the same parallels will be found; and in the evolution of the system, which constitutes its leading character, in

the formation of the spinal marrow and brain, those parts common to the lower vertebrata precede and are perfected before those of the higher classes. Thus, as I have already stated to you, the spinal marrow, the medulla oblongata, and optic tubercles, precede the appearance of the cerebral lobes: arrests in the progress of development consequently produce the varieties of acephalous, podencephalous, and anencephalous monsters.

It is unnecessary for me to proceed farther with these illustrations. I have referred to them on the present occasion to prove to you the value to physiology of a sound obstetric education, and to show you that, in your future sphere of duties, many opportunities may present themselves of aiding these inquiries, which you may profit by or lose, precisely in proportion to your previous knowledge of the subject. I feel the less hesitation in claiming your attention to this part of your obstetric education, because, as pupils of this College, you are especially fortunate in having, as your Professor of Physiology, a gentleman pre-eminently distinguished for his intimate acquaintance with embryology. This part of your education you will therefore receive from him; and in my future courses I shall only allude to so much of it as may be necessary to illustrate questions of practice. In doing so I am acting in accordance with the wishes of this College; but were it otherwise, I should certainly wish that it should be so, and would feel some little reluctance to recapitulate imperfectly what you have already had so ably explained to you: I would feel that I scarcely had a right to do so.

*"Neque ego ausim, coronam detrahere cum multo laude merentem."*

If I have succeeded in showing you that midwifery opens a wide field of facts to the physiological inquirer, I shall direct your attention to another object of scientific research, and shall endeavour to satisfy you that parturition itself affords as beautiful an illustration of mechanical contrivance as any that have been offered in natural physics.

Man is the only animal that assumes the perfectly erect position, and the development of his brain is greater, in proportion to his size, than that of any animal of his class. These two facts, however advantageous to him on every other point, become to the human female a leading cause of difficulty in giving birth to her offspring. From the fact of the position being perfectly erect, the pelvis of necessity becomes a centre of motion, itself immovable, and acted upon by opposite forces. As it supports the weight of the body above, and like an arch presses down upon, and is resisted by, the femoral bones below, it is essential that its whole construction be remarkably firm and

compact. It is composed of three bones, united by one of the strongest articulations in the human body : the passage therefore of a body through the pelvis, that would entirely fill, or having any tendency to expand it, must be proportionably difficult.

Besides this, as the pelvis forms the lower boundary of the abdominal cavity, and upon it the free contents of the abdomen rest, it is essential that it be so constructed that these contents cannot fall through it in case of shocks ; and as it is not actually closed below, it should be as contracted in the outlet as circumstances will permit. Such is its construction. We find that portion above the brim sufficiently open, and forming, with the soft parts attached to it, a perfect basin, terminating the abdominal cavity ; but below the rim the pelvic cavity is first withdrawn from the line of direction of the abdomen ; and while the axis of the false pelvis is nearly vertical, that of the brim and cavity forms a considerable angle with the perpendicular. The contents of the pelvic cavity are thus removed from the effects of shock, the influence of concussion being thrown forwards upon the pubis ; hence the frequency of inguinal and femoral hernia in comparison with that of the pelvic viscera.

Not only is it thus withdrawn, but the cavity itself is partially closed : the ischial surfaces converge, and a resistance is at once offered to the passage of any large body through it. The child's head, therefore, is an obvious difficulty, and some mechanical advantages are required in order that its passage be at all accomplished. It is my wish to explain how nature effects this purpose.

In the most natural position the child's head is so placed that its least measurement is adapted to the widest of the brim ; to effect this the head of the child is pressed down upon its chest as it enters the pelvic cavity ; the occipito-parietal portion is consequently most dependent ; but if it continued to descend in this direction, the convergence of the ischia would at once present an impediment ; it is necessary, therefore, that it be changed to gain the widest space of the cavity. In consequence of the sacrum retreating, and forming a hollow below the brim, this space is in the antero-posterior direction ; a rotation must therefore be accomplished by which the head may be placed in that position. The construction of the pelvis is such as to compel the head to make this turn.

Although in the dry pelvis its transverse measurement is greatest, yet when covered by the soft parts the oblique is found to be so ; the head therefore passes the brim obliquely, and is at first arrested by the ischia, which present to it a smooth surface, so contrived as to form a double plane slightly inclined in opposite directions : the occipital

portion then descends upon the anterior plane towards the arch of the pubis : the frontal moves upon the posterior plane towards the hollow of the sacrum. The shape of the pelvis at this part is calculated to facilitate this movement. Anteriorly the obturator foramen affords more room than it had before, and when it arrives at the pillar of the pubic arch it is so bevelled as to facilitate its entrance into that space ; while posteriorly the sacro-sciatic foramen offers a similar advantage, and the short sacro-ischiatic ligament becomes also a species of inclined plane, upon which the forehead glides into the hollow of the sacrum.

When this rotation is effected the head will lie in the antero-posterior position, and a new motion of rotation commences still more remarkable. The head has now to overcome the narrow outlet, completely closed in by a very resisting perinæum. This is accomplished by making the head act as a lever ; the pubic arch becomes the fulcrum, against which the occiput rests ; and round this the head revolves, passing with its greatest measurements successively along the hollow of the sacrum ; it then meets the resistance of the coccyx and perinæum, which, by frequently repeated efforts, it ultimately dilates to an extent not before suspected, and at length the child enters into the first period of respiratory life. I shall hereafter have to refer to this mechanism of parturition more particularly.

I have directed your attention to two points of view in which the profession you are about to enter is calculated to give you a lively interest in its study. I would ask you now to consider it with me in another light, as a subject of practical importance, which should not be treated as a pursuit so easily followed as to need but little attention. One or two examples will be sufficient to convince you of the contrary, and to illustrate where the difference between the educated and ignorant practitioner would at once be apparent. I shall take one of the varieties of uterine hæmorrhage, that which arises from the circumstance of the placenta being situated immediately over the mouth of the womb. When this occurs it constitutes a case of the most dangerous character, because we have no means of arresting the hæmorrhage, unless by removing the child : the more the labour pains dilate the mouth of the uterus, the greater the flooding. It is therefore of the utmost consequence to be able to ascertain this situation of the placenta early, in order to be prepared to deliver at the proper time. How can you do so, unless you are accustomed to the peculiar feel which the uterine surface of the placenta presents ? My assistance has been called for in more than one instance where the supposed placental presentation was only a large clot of blood retained between the membranes of

the child and the uterus, long enough to feel as firm and resisting as the afterbirth. If the mistake had not been discovered, you can readily judge what a serious blunder would have been committed by making an attempt to pass the hand into the uterus to deliver the child. I could record instances in which the life of the patient had been lost from an error on the opposite side; in which the situation of the placenta was unknown until too late, and the patient sacrificed to indecision and want of tact. Such a result is too serious not to urge it on your consideration as an argument in favour of the importance of acquiring a practical knowledge of midwifery.

Another example might be taken from those positions of the child called cross-births, or shoulder presentations. In this, as in the former instance, promptitude is essential. The educated practitioner will at once detect this position, and be prepared to deliver the child as soon as he can safely pass his hand into the uterus; but this position is by no means so easily detected that the unpractised hand will at once discover it. When the subject comes properly before us, I shall take occasion to point out the different sources of error: for the present I shall allude to two. When the shoulder presents, and that the hand and arm are still retained in the uterus, it bears, in many points, a strong resemblance to the breech-presentation: it has been mistaken for a breech, and consequently left far too long to the natural efforts for security. Again, the hand and arm will sometimes descend with the head, and often so much before it, that the hand will appear at the external parts long before its descent. I have known this supposed to be an arm-position, and only the mistake were pointed out, would have been a reason for making the attempt to turn the child. In the progress of this course I shall have to point out other similar instances which I am persuaded will be sufficient to convince you, if any doubt remain, that midwifery, viewed as a practical study, demands from you as much attention as any other branch of your professional education; while I think you will be satisfied that the consequences which follow from ignorance and presumption are even more serious in obstetrics than in other medical pursuits.

If then, gentlemen, you will admit with me, that the studies you are about to enter upon are of a character sufficiently elevated to stimulate your zeal, and sufficiently important to command your industrious attention, it remains for me to offer you a very few remarks on the mode by which it appears to me you would best acquire a competent knowledge of it, as well as to guard you against some errors respecting it, which are, unfortunately, too prevalent.

There is one feature peculiar to midwifery in which it differs from the other branches of

medical study. In your observation of disease, whether it be medical or surgical, every single case that comes under your notice forms a new subject of attention; between different cases there may be few points of resemblance, and a very few cases of one disease, if accurately observed, will hardly fail in making you acquainted with it. It is not so in midwifery. You will meet case after case of an apparently similar character; the junior student is consequently often led to believe that there is little to learn in obstetrics. He takes for his motto "*ex uno disce omnes*;" and in this indolent security is often surprised into a new and untoward series of difficulties, which will equally excite his alarm and bewilder his judgment. You should therefore remember that it is only by a patient observation of those cases of everyday occurrence, by a close study of the phenomena of natural labour, and by a careful collection of those facts which are always within his reach, that the practitioner can be prepared to understand and to remedy the exceptions which may arise. It is to the *habit* of observation thus acquired, to the "*tactus eruditus*" by frequent practice obtained, that the student should calculate upon the certainty of his success in future practice. It is essential for you to understand the theory of your subject; but I would caution you against indulging too much in theoretic inquiries. The present age may well be called the age of theory; nor have we escaped its general influence: even with us theories vegetate in such wild and abundant luxuriance, as by their very number and intricacy to conceal from view the commonest lessons of experience. If not useful, it is at least amusing, sometimes even fascinating, to follow the fine-spun reasoning upon which some theories are founded. To examine such curious questions are much more interesting than to sit at the bedside of a patient for hours, contented to watch the progress of a labour of which you think you know, and have seen enough already; but, gentlemen, I would repeat to you, be not deceived; the more you advance in the knowledge of your profession, the more you will perceive the infinite value of these very cases. You will find each presenting you a new matter for observation; and that it is by a close attention to those cases which recover well, and which need but little assistance, that you will at once perceive an unusual symptom, or be able to obviate a threatening danger. If you are not accustomed to the pulse, the feel of the abdomen, the tongue, the natural sympathy of the stomach, or the general aspect of the patient, whose recovery is favourable; the gradually increasing heat of the pulse, the commencing tenderness and irregularity of the abdomen, the unhealthy irritation of the stomach; nay, even the distension of the

bladder; all will escape your notice until they become so obvious that you could have wished most heartily that you had seen the coming tempest a little sooner. In the usual routine of ordinary cases, there are many points which, if attended to, will convey to you much useful information.

The stethoscope will afford an extensive range of practical observation. The ear, like the other senses, requires practice to discriminate. A musician will detect a discord which would escape the uneducated ear; and thus you will not be disappointed if you find it difficult in your first attempts to distinguish the uterine from other similar sounds which may be heard in the abdomen. Persevere, and you will soon find that your time has not been misspent, in the readiness with which you will detect the placental murmur and pulsations of the foetal heart. You have then established not only an evidence of the life you are about to aid in bringing into the world, but you have opened for yourselves a new field from which you can glean many interesting facts. The action of the foetal heart before and subsequent to its respiratory life, the foetal as compared with the maternal pulsations, the variety in the positions of the placenta, may all be ascertained; and though you may not at once perceive the immediate utility of such experiments, you will hereafter find their value in determining questions connected with the general physiology of the circulation, as well as with practical midwifery.

You will also learn to discriminate many causes which, in your first attempts, excited confusion. The large arteries of the abdomen, when compressed, produce a bruit, which you will soon distinguish from the placental soufflet. The pulsations of the maternal heart heard through the abdomen have been confounded with the foetal: your practised ear will detect these and other sources of deception; and it is possible you will discover other errors which have not yet been observed.

I might also allude to the varieties which are met with in those presentations which are classed as natural. I have given you a general outline of the manner in which the head of the child passes through the pelvis. When we shall have occasion again to allude to this process, we will find that, in this as well as in every thing else, nature will not be restricted to an uniform rule, but that the head passes through the cavity in different and often opposite directions. As these varieties are always within the power of observation, one would suppose that the nature of these deviations must be already quite determined; and yet, among obstetric authors, there is nothing upon which there has been more contrariety and mistake. The

older writers in midwifery always made the head to pass in the conjugate measurement of the pelvis—a direction which it very rarely takes. More lately this error was corrected; and Baudeloque (whom I might call the Denman of France) has given a description of these presentations with much apparent accuracy. He has been indolently followed by a host of writers, who judged that he must be right simply because, in their study, with the naked bones before them, the explanation appeared ingenious and consistent. It was reserved for the late distinguished Naegele, in an hospital by no means large, and with a very limited number of facts, to dispute the whole of their description. Being interested in the beautiful mechanism of parturition, anxious to observe it, and determined to judge for himself, he found so many exceptions to the rule he was taught, that he began to doubt its truth: further observation satisfied him it was erroneous, and at length he boldly and successfully denied the statements which were made. I quote him, therefore, to you as an example quite within your power to follow, and one which proves the value of observing the phenomena of ordinary natural labour which are presented in every case you attend.

I have thought it right, gentlemen, to bring before your notice these different subjects of study, in order that it may be an inducement for you to observe these ordinary cases, because teachers generally find that, whether it arises from a desire for novelty, or from an erroneous impression as to their future practice, pupils almost always are led to neglect what is to be met with every day, while they rush in crowds to witness what they may never be called upon to perform. The experience of those surgical professors whom, elsewhere, I have had the opportunity and privilege of knowing, has always been, that too frequently, while the common course of hospital duties are negligently attended to, their pupils fly to the operating theatre; and that case which it is least likely they may even again meet with, is that which will bring the largest crowd. It is hardly different with midwifery: an interest attaches to the performance of an operation that an ordinary case can in no way excite; and I have known the greatest discontent, when an opportunity of this kind was lost, manifested by pupils who could scarcely be persuaded to perform their necessary duties.

There cannot be a more dangerous mistake: it shall be my duty to make you acquainted with all the operations in midwifery, but, at the same time, permit me to assure you that the best practitioner in midwifery is he who has the fewest operations to perform; and when you will know that in the largest hospitals, where, of course, cases are admitted which you will seldom or ever meet

with in private, the proportion of operations do not exceed 1 in 100 cases, you can readily decide upon the number of times you may be called upon to operate. It is true it may be objected that the young practitioner may be required to operate in the outset of his career, and when he least expects it; but I have no hesitation in replying that the facility with which an operation is performed depends much more on the nicety of touch which you have previously acquired; by which you know every point to which you apply the instrument; by which you are conversant with the relative position of all the parts; than by ignorantly thrusting it, you scarcely know where, in the feeble attempt to imitate what you may have seen, without any thing to guide you but what, at the best, would be but a lucky chance. If you have previously laboured at the bedside, and have made yourself fully conversant with the phenomena of parturition, you will not only be best prepared to avoid an operation, but, if you should have to perform it (even for the first time) in place of finding it difficult, you will be rather surprised at the facility of your progress. In fact, the embarrassments and bad success of operations in midwifery are caused, with few exceptions, not so much by anything very complicated in the operation itself, as by the operator's want of tact—a quality not to be acquired by frequent operations (for in such a case he must make operations for himself), but by patient attention to those cases I have already alluded to, and which can alone form the basis of a successful practitioner.

I have felt it my duty to lay before you in this manner the nature of the profession you are about to study, as well as my views of the method by which you will best acquire an adequate knowledge of it. In the course of instruction you are about to receive, it is my wish, and shall be my endeavour, not to confine it to the precincts of this theatre; but, as far as lies within my power, to aid your clinical observations. I feel assured you will appreciate my desire to guide you in this the only true course of professional improvement; and if I have succeeded in proving to you that obstetrics holds out sufficient inducements to allure you to its study, and in its practical results is too important to be treated with indifference or neglect; if I may expect your co-operation in patiently observing and recording facts for their own sake; I have very little hesitation as to the result. If I were to look back into the history of my profession, and in the biography of its most eminent cultivators seek for the leading principle of their reputation, it would not be found in the brilliancy of their genius, nor the power of their talents, but in their patient and persevering attention to

every-day facts. Amongst them were those who, perhaps like some of my hearers, entered upon their professional career under difficulties which, at the time, appeared almost insurmountable: they were contented, however, to struggle patiently from step to step until they overcame the obstacle immediately before them; instead of making this their resting-place, it only enabled them, with a surer footing, to grasp some higher difficulty, until at length, by persevering and watchful industry, they attained the highest object of their ambition, in being placed at the head of their profession, as well as being considered its best benefactors. They did not seek to gain celebrity *per saltum*, and were, therefore, not discouraged by indifference to their early exertions. The growth of their reputation, like the oak, was gradual, its stability permanent; not shooting up suddenly to the full height of professional distinction, but often remaining for a long time in neglected obscurity. Attempts were often made to trample on the rising plant; but these efforts only served to increase its strength, until at length, overcoming all opposition, it attained the full vigour of maturity, and thus they diffused around them the fruits of a cultivated mind with a luxuriance that equally commanded admiration and respect.

I only ask you, gentlemen. (such of you, at least, as purpose to make midwifery the especial object of your attention), to follow in their *first footsteps*, to imitate their *early efforts*. It shall be my object to assist your endeavours to the utmost of my power; and if the humble individual who has now the honour to address you is in any way the means of contributing to your future successful career, it will be a rich and gratifying reward for any exertions which may now be made to accomplish so happy a result.

---

CLINICAL LECTURE  
ON  
DELIRIUM TREMENS.

*Delivered at King's College Hospital,  
Nov. 20, 1841,*

BY GEORGE BUDD, M.D., F.R.S.,  
Professor of Medicine.

---

I wish to call your attention to the case of John Embleton, a sailor, who was brought into the hospital on the 16th, in a state of violent delirium.

He arrived in London from St. Petersburg three weeks before; when, his ship having been paid off, he began drinking. He was constantly drunk for twelve days, and during that time scarcely tasted solid food. When his money was spent, he pawned his watch; and when the supply from this too

was exhausted, he was obliged to leave off drinking. This was about nine days before his admission to the hospital.

From that time he had no appetite, and scarcely any sleep. On the 13th, after six sleepless nights, he was very desponding and irritable. The next day he was in a state of raving delirium. He said thatadders were about the bed attempting to bite him; and fancied he had murdered his wife. During the 15th he was more tranquil, but in the evening he became again violently delirious, and continued so throughout the night. He attempted to climb the bed-posts, taking them for masts.

At the time of his admission he was very violent, and fancied he was surrounded by frightful serpents, that were constantly trying to bite him.

One fluidrachm of tincture of opium was given him immediately, and ordered to be repeated every hour for three successive hours, if it should not procure sleep before. Immediately on his awaking he was to have a mutton chop, and a pint of porter.

He fell asleep after the first dose of opium, and slept for several hours. When he awoke he took his mutton chop and porter. The opium was not repeated, but he slept quietly great part of the night. The following morning we found him perfectly rational, and his appetite had returned. He was ordered middle diet and porter, and a dose of opium at night.

He had no return of delirium, and left the hospital on the 20th.

The case of Embleton is a fair specimen of the delirium brought on by excessive drinking. During the years I was physician to the Dreadnought, I had constantly cases of this kind under my care. The frequency of delirium tremens in sailors is very readily explained.

When a ship returns from a long voyage, the crew are paid off. A man receives at once £40, £50, or £60, and is immediately laid hold of by the most despicable of human beings—the *crimps*, as they are called, or the agents of the keepers of the filthy lodging-houses in the neighbourhood of Wapping. He is taken to one of these houses, and kept in a state of constant intoxication for a fortnight or three weeks. By this time his money is generally spent. His clothes are then pawned, and this supplies him with drink a day or two longer. When this last resource fails, when the system of robbery can be carried on no longer, the supply of drink is stopped, and the sailor is turned adrift to shift for himself. In a few days he is brought to the hospital in a state of delirium tremens.

I have known sailors, who had received as much as £70, reduced to complete destitution in the course of two or three weeks.

During the time they are kept in this state of intoxication they eat nothing, often not so much as a morsel of bread, for days; they live, as they express it, on the liquor.

When they are brought to the hospital, the condition of all these men is very much alike. The face is flushed, the eyes are suffused, and there is often a peculiar wildness in their air and manner, even when there is no actual delirium. The tongue is pale, moist, and indented; and the hands as well as the tongue are very tremulous. Appetite is quite gone, and they have generally repugnance for food of every kind. In spite of this nervous agitation the pulse is steady and tranquil, and very seldom increased in quickness.

But what is characteristic of the disease, as characteristic as the trembling, is the loss of sleep. They all tell you that they have had no sleep for nights; and that the moment drowsiness comes over them, or even without this, at the approach of darkness only, they are haunted by visions of the most frightful kind: they see serpents about the bed, and are pursued by devils of every size and shape. The constancy of these horrid apparitions has furnished a name to the disease. The term, in fact, by which it is known to sailors, and a very appropriate one it is, is the "horrors."

This name has, no doubt, passed down through many generations of sailors. Smollett uses it in *Roderick Random*. Smollett, in early days, was a surgeon's mate in a man-of-war, and sketched Roderick from the life. Roderick, in relating his history, says, "I awaked in the horrors, and found my imagination haunted by such dismal apparitions, that I was ready to despair." This very properly happens to Roderick, a day or two after he set sail. In delirium tremens from drinking, the patient generally gets more violent, and is in every respect worse, a day, or two or three days, after he has left off drinking. Sailors are themselves aware that a glass of grog steadies them when in this condition.

In some cases, the men are more violently delirious: they are continually vociferating, and talking in the wildest and most incoherent manner; they are in a state of great agitation and tremor, and their body is bathed in sweat; yet even in these cases the pulse is generally calm and steady.

The character which the delirium assumes is that of hallucination. They see unreal objects, and these objects are almost always of a frightful kind. In some cases, but these are rare, the illusion extends to the sense of hearing. They hear the objects by which they are haunted, talking, and occasionally calling them by name.

But hallucination is more rare for the sense of hearing than for that of sight; pro-

bably because more vivid impressions are received through the eye than through the ear. Ghosts are more frequently seen than heard. Dr. Abercrombie thinks that dreams are chiefly occupied with objects of sight. In his work on the Intellectual Powers, he says, "I am informed by a friend, who is a keen sportsman, that he often dreams of being on a shooting excursion; that he starts his game and points his gun, but never succeeds in firing it. It sometimes seems to miss fire; but in general there is something wrong in the lock, so that it cannot be moved."

It was probably the poet's own experience that frequent and deep potations give birth to hallucinations of a frightful kind, that suggested to Burns the scene of the witches in *Tam o' Shanter*. Tam, returning late after a drinking bout, passes by All Hallowe'en Church, in which he sees warlocks and witches in a dance, with Auld Nick for their piper. The objects with which the fancy of the poet has filled up the picture are certainly frightful enough:—

"Coffins stood round like open presses,  
That shawed the dead in their last dresses;  
And by some devilish cantrip slight  
Each in its cauld hand held a light,  
By which heroic Tam was able  
To note upon the haly table,—  
A murderer's bane in gibbet-airns;  
Twa span-lang, wee, unchristened bairns;  
A thief new cuttit frae a rape,  
Wi' his last gasp his gab did gape;  
\* \* \* \* \*  
A garter which a babe had strangled;  
A knife a father's throat had mangled,  
\* \* \* \* \*  
Wi' mair o' horrible and awfu',  
Which e'en to name wad be unlawfu'."

This description, though highly coloured, is true to nature; but such hallucinations usually arise after prolonged excess, and not, as Burns makes it, after a single sitting.

Another character, very general in these cases, which seems allied to the frightful nature of the hallucinations, is despondency and a tendency to suicide. Even in slight cases I have known men suddenly burst into tears while I have been questioning them.

Well-marked cases of delirium tremens are easily recognized. Their characters are so striking, that, taken with the previous history of the patient, they can scarcely be mistaken; but this is not the case with the slighter degrees of the same affection. These are marked only by lowness of spirits, and inability to sleep; or by sleep which is interrupted by frightful dreams. It is a condition which is familiar to many by the name of the "blue devils," which, in the majority of cases certainly, must be ascribed to excess in drinking. Men of jovial habits—who take what is called a cheerful glass, and enjoy company and good cheer—are re-

markably subject to the blue devils. They are low and desponding in the morning, and their nights are sleepless, or their sleep is broken by dismal dreams. In the language of sailors, they have the "horrors." It is the temperate man only whose spirits are uniformly good.

Embleton told us that the objects by which he was haunted, though continually shifting their shapes, were always of a blue colour. I have often heard sailors make the same remark; and I am inclined to think that this is a very general character of such apparitions. Müller, speaking of phantasms, says that they are generally divested of colour.

I have said that in delirium tremens, the pulse, except after considerable muscular exertion, rarely exceeds its ordinary frequency. In cases in which it does, there is generally inflammation of some internal organ.

The organs most frequently inflamed are the stomach and the lungs.

It is not at all uncommon to find a man affected with the horrors, who, in addition to the ordinary symptoms—the delirium and the trembling—has frequent vomiting, a furred tongue, and a quick pulse. Such symptoms generally indicate inflammation of the stomach, and are of very bad augury; because, when they are present, the patient is unable to take solid nourishing food, which is a very important part of the treatment, and, indeed, frequently indispensable to recovery. In a case of this kind I have found the mucous membrane of the splenic extremity of the stomach reduced to a mere pulp.

The *lungs* are much less frequently inflamed than the stomach; but I have met with two or three instances of delirium tremens which proved fatal, apparently from the occurrence of pneumonia.

In none of the cases in which I have made an examination after death—in all, four or five—have I found any evidence of inflammation within the head, other than effusion of serum under the arachnoid. The symptoms do not depend on any inflammatory affection of the brain, but on exhaustion, consequent on over-excitement, and in part, perhaps, on the condition of the blood. We can hardly suppose that the blood should not become altered, and for some time remain so, by the continual admixture of spirits. The spirit undoubtedly exerts some degree of chemical influence.

Sailors, in whom I have chiefly observed delirium tremens, are men whose constitutions are not broken by habitual intemperance, but strong, robust men, most of them in the prime of life, who get drunk only while they are in port. From these circumstances the affection in them is somewhat different from what it is in the habitual drunkard; but the main characters and the indications of treatment are alike in both.

The chief remedy is *opium*; but it must be given in large doses, so as to procure sleep. In small doses, it does comparatively little good. When a man has been for days in a state of nervous agitation, and has had no rest for several successive nights, our object should be to procure *sleep*. I have often, as in the case of Embleton, seen a man in a state of raving delirium fall asleep under the influence of a large dose of opium, and, at the end of some hours, awake perfectly rational.

The plan into which I settled for the treatment of delirium tremens, such as I used to meet with in sailors, is to give one drachm of tincture of opium, every hour, for three or four successive hours, if the patient should not fall asleep before; and, as soon as he awakes, to give him a mutton chop, or some solid food.

I have already told you that these men, as long as their drinking bout lasts, eat nothing; and although, while the state of excitement continues, they have great seeming strength, and in some cases can be mastered with difficulty, yet, as soon as it subsides, they are always in a state of debility, and evidently require nourishing food. This is indicated, even while the delirium persists, by the condition of the tongue, which is almost always, in these cases, more or less indented; a condition you will generally find associated with states of debility.

Before they have slept they are unable to take food; their appetite is completely gone; a circumstance which must be attributed not to the state of the *stomach* merely, but to that of the whole nervous system; for the appetite generally returns when the system has been refreshed by sleep.

I consider this point—to give as soon as possible some solid food—a most essential one in the treatment; and have almost invariably found men get worse in cases where, from some mistake or neglect, it has been omitted.

I have said that opium should be given in large doses; but even these sometimes fail in procuring sleep. It is indeed astonishing how much of it can be taken by persons in this state of nervous excitement without sensible effect. In one instance in which I had left directions that a drachm of laudanum should be given every hour until the patient slept, 3x. were given in the course of 24 hours, without producing the slightest sign of narcotism; and it was only after the last dose that the patient fell asleep.

A similar insensibility to the ordinary effects of opium is witnessed when it is given to relieve very severe pain or spasm. Doses, which in other circumstances would be dangerous, may be given not only with safety, but without apparent effect. But although large doses of opium may be given, and are even required, to relieve severe pain,

or to control violent spasm, or to calm the nervous excitement of delirium tremens, you must not suppose that its employment requires no caution in these cases. The rule generally laid down, and I believe it is a good one, is to discontinue the opium when it has produced contraction of the pupil. Different narcotic substances produce different effects on the pupil. Belladonna dilates it; the first effect of opium is to contract it. Contraction of the pupil shows, therefore, that the system is powerfully affected by the drug, and should caution us against its further employment.

When the opium acts favourably, when it procures a quiet sleep of several hours, the benefit resulting from it is remarkable: the delirium has ceased, the agitation has subsided, and, if the appetite have also returned, the patient is convalescent. But in some cases, opium, in however large doses we give it, fails in producing this effect. It calms the patient in some degree, and brings on a dosing state, which is often interrupted by startings, and from which the patient arises but little refreshed.

In many such cases, where opium had failed in composing the patient, I have seen admirable effects from wine or brandy, especially where the patient had left off drinking for several days. The delirium and nervous agitation seem to result partly from the sudden withdrawal of the stimulus. I have already remarked that the men are generally much worse two or three days after they have left off drinking, and that they are themselves aware that a glass of grog steadies them. But I would only give wine or spirit when opium had failed to procure sleep, and when the delirium had persisted some days after the patient had discontinued drinking.

Another important point in the treatment of delirium tremens is, that the patient should be removed as much as possible from all causes of excitement: his room should be quiet, and few persons should be allowed to visit him.

The last point that I wish to impress on you, is, the great importance of narrowly watching the patient. I have already stated to you that in this disease, even in its lighter shades, the patient is possessed by gloomy ideas, and has often a strong propensity to suicide. He should therefore be narrowly watched, and every instrument by which he can effect self-destruction should be placed out of his reach.

For want of these precautions, we had a very tragic scene on board the Dreadnought, in the summer of 1838. Three men, Parrymore, Baily, and Forster, were brought into the hospital the same day in delirium tremens. They were treated in the usual manner; and I believe a straight-waistcoat was placed on each. The day after their admission, Parry-

more was very much better, and gave me a clear account of many particulars of his case—as, of the voyage he had last made, the time he had been in port, and the money he had spent. All restraint was in consequence left off. The same evening he cut his throat with a clasp-knife, which sailors generally carry about them. The surgeon, who was in immediate attendance, found him sitting up in bed, bleeding profusely, and still hacking away at his throat, to all appearance perfectly insensible to pain. The divided vessels were tied, and the hæmorrhage stopped; but he died at the end of a few days, from the secondary effects of the wound.

Baily also, the day after admission, gave me a clear account of many particulars of his case; and I considered him in no danger. The excitement and commotion in the ward consequent on the attempted suicide of Parrymore, again threw him into the most violent delirium, in which he continued for two days. On the fourth day after his admission, I found him very hoarse from vociferations, but tranquil and rational. The strait-waistcoat was taken off, and orders were given that he should be narrowly watched. The same evening, however, he eluded the vigilance of those about him, and threw himself out of one of the port-holes into the Thames. A boat was immediately sent after him, and he was soon picked up, swimming lustily between the Dreadnought and the shore. When in the boat, he struggled violently to throw himself again into the river; and such was his muscular power, that it was with the greatest difficulty the two men in the boat could master him. They succeeded, however, in doing this; but Baily, apparently exhausted by his struggles, almost immediately expired. He was lifted into the Dreadnought a corpse.

We could not examine the body before a coroner's inquest had been held; and as this was not done for some days, and the weather was very hot (it was the middle of July), the body was too far advanced in decomposition to enable us to form a satisfactory opinion of the cause of his sudden death. I believe, however, that he died of pure exhaustion—the consequence of the powerful efforts he had just been making. He was one of the most muscular men I ever saw, and had no organic disease.

These cases, as you might expect, have made me very watchful over patients in delirium tremens. They should not be left a moment unguarded; and in hospitals, where they cannot have a person in constant watch over them, I would always put on a strait-waistcoat, whenever I could do so without using violence, or increasing the agitation of the patient. I make this exception, from a sense of the ill effects of excitement, and of the exhausting influence of great muscular exertion.

But delirium tremens, or at least a condition very similar to that brought on by excessive drinking, may be caused by any great shock to the nervous system, especially by surgical operations, or severe injuries.

When induced by this last cause, it is called traumatic delirium. But its characters are precisely like those I have before described:—nervous agitation, trembling, inability to sleep, and hallucinations, generally of a dismal kind.

The insensibility to pain (which I have before noticed in the case of Parrymore) in these cases is truly remarkable. Dupuytren, who has left a beautiful description of nervous delirium, says, that he has known patients in this state, with a comminuted fracture of the leg, slip off the bandages and walk about, using the broken limb without evincing the slightest pain; and others, who had been operated on for hernia, introduce their finger into the wound, and amuse themselves with twisting about the gut, as if they were doing it on the dead body.

He also particularly remarks, as all writers on the subject do, the state of the pulse. He says, “the most remarkable symptom, in the midst of this disturbance of the intellect, is the calm of the circulation, and the absence of every febrile symptom. You see a patient furious; his face covered with sweat; his eyes glistening; his cries heard at a distance: you believe him affected with the most intense arachnitis. Approach him: his pulse is calm and regular; and the state of his skin removes every suspicion of inflammation.”

The treatment in these cases is the same as in the delirium tremens from drinking. Opium is the chief remedy.

Dupuytren gave it in injections. He says that a dose of opium administered in this way has as much effect as three times the quantity given by the mouth. He explained this by supposing that when opium is given by the mouth, it is, in some degree, altered, and rendered less effective, by the juices of the stomach.

But, in other circumstances, you will occasionally meet with a condition of the nervous system very similar to delirium tremens.

In the 19th vol. of the *Med. Chir. Trans.* is a paper by Dr. Seymour, containing three cases of mania, successfully treated by morphia. They all occurred in women.

In the first case the woman became affected, after suffering severe distress, in consequence of the death of a relation, who died in her presence. She was occupied by gloomy ideas, and a belief of having committed indescribable crimes. Her nights were sleepless, and there was continual watchfulness, and restlessness of the body. Her pulse was not weak, and her bodily health was unusually robust. She recovered

in six weeks, taking a grain of acetate of morphia every night.

In the second case the history is obscure. The woman had been bled and blistered for what was conceived to be inflammation of the lungs. She was extremely violent; fancied that her children were murdered, and their spirits returned to torment her. Her sleep was broken. There was no fever. She recovered under the same treatment.

In the third case there was great previous affliction; and the mania came on after childbirth. The symptoms were nearly the same, and she recovered under the same treatment.

It is impossible not to perceive the analogy between these cases and those of delirium tremens. There is the same absence of fever, the same restlessness, the same want of sleep, and the occurrence of visions and dreams of the same character, in both.

All the instances I have mentioned agree in the absence of fever, and in the regularity of the functions of the body in the midst of the general nervous disorder; in the presence of gloomy ideas and frightful dreams.

It seems, then, probable that opium will be beneficial whenever there is a combination of these conditions. Dr. Seymour says, "morphia appears to be of more use in what is termed melancholia, where the mind is tortured by imaginary want, ruin, or crime, than where the derangement partakes of more brilliant ideas; as of superhuman knowledge, dexterity, or wisdom: or than in those cases where one single idea occupies and absorbs the mind."

I have seen one or two instances in which a state very much like that in the cases related by Dr. Seymour, resulted from excessive study.

One was in a man with whom I was well acquainted at Cambridge. He became insane after an attack of scarlatina in the summer of 1828. He had been reading excessively hard, and was much exhausted, when he was attacked with scarlatina on his way to the Lakes, to spend the summer vacation. He was laid up with scarlatina a fortnight; and soon after was placed in an asylum, where he remained two years. At the end of this time he was released, resumed his reading at Cambridge, and took a wrangler's degree in the year after that in which he would have taken his degree in the ordinary course.

The character of his insanity was like that of persons in delirium tremens. He fancied that he was constantly surrounded by devils; and even now, ten years since leaving the asylum, he is convinced of the reality of these apparitions.

My attention has lately been called to another case of the same kind. A man, like the former, became insane after hard

reading; and his insanity was of the same character. He was placed in an asylum, where he continued some years. Since his release he has turned author, and the books he has written display considerable talent.

I have little doubt that such cases are allied to delirium tremens—that the insanity is the cause of nervous exhaustion—and that it is best treated by opium, generous living, and quiet; means so efficacious in the various forms of delirium tremens. It would certainly afford a medical man a high gratification to cure a case of this kind—to restore an educated and gifted man to his family and himself; but there is very little satisfaction in curing a man of the delirium that results from drinking, because he is almost sure to get into the same state again. The only chance for him is to become a tee-totaler.

Experience of the "horrors" has certainly very little influence in deterring sailors from a repetition of the excesses by which they are brought on. Embleton told us that he had had the "horrors" twice before; and men have often confessed to me that they have had them as many as seven or eight times. I am afraid, therefore, that Burns's parting advice, in *Tam O'Shanter*, has been lost on the lovers of tippeny:—

"Whae'er this tale o' truth shall read,  
Ilk man and mother's son tak heed;  
Whene'er to drink you are inclined,  
Or cutty sarks rin in your mind,  
Think, ye may buy the joys owre dear;  
Remember Tam O'Shanter's mare."

## ON ARTIFICIAL CLIMATES,

FOR THE RESTORATION AND PRESERVATION  
OF HEALTH: TO BE CONSIDERED UNDER

I. *The atmospheric treatment of the lungs.*

II. *The atmospheric treatment of the lungs and skin.*

BY JULIUS JEFFREYS, F.R.S., &c.

[Continued from p. 163.]

*On instrumental means for producing  
an atmosphere genial to the lungs  
when in an irritated state.*

THAT the mind should be excited to an earnest desire to command those artificial varieties of atmosphere respirable with comfort and benefit by the pulmonary sufferer, little, I would hope, need be added to the preceding arguments, although they by no means comprise all that is of importance to the question.

That we may be guided rightly in the choice of practical measures, it is necessary to keep present in the mind the points of chief consideration.

Briefly, then, to recapitulate. It has appeared, in the first place, that many of the severest symptoms in chronic diseases of the lungs are, in a great measure, due to the condition of the air respired; and that we must not form any judgment against this conclusion on finding a limit set to our trials by the effects of an atmosphere which envelopes the whole body; since, with sound reason, we may expect very different results when the atmospheric remedy is applied only to the part affected: therefore that our measures should provide a different atmosphere for the lungs, while irritable, from that which invests the body.

Secondly, that our measures should provide for the exhibition of our atmosphere being unremitted, and unattended to by the patient.

Thirdly, that whereas breathing an untempered air habituates invalids to a suffocative kind of respiration, which leads to an unhealthy state of the blood and system generally, and thus reacts upon, and aggravates, the malady itself, it is to be desired that our measures should supply air of that bland quality by which it may be freely respired, and in quantity sufficient for the freest demand; and that they should, at the same time, ensure the discharge, with equal freedom, of all air rendered stale by being respired.

Fourthly, that where they are to be employed for soothing the system into rest at night, our measures should not interfere with the accustomed retirement to bed, and the recumbent position; nor with the unrestrained movement of the body.

Fifthly, that the same or other measures should be adapted to the patient's movements about a house in the day-time, since, upon the grounds established, I would hope by abundant argument, the exhibition to his lungs of the modified atmosphere should be *unremitted by day as well as by night*, so long as any cough or other atmospheric symptom is present, manifesting the general atmosphere to be unsuited to the excitable state of the pulmonary membrane. In every case of chronic disease there are periods of many days together, when it is my firm conviction,

supported by frequent observation, that a patient would be greatly benefited by respiring, night and day *unremittedly*, an atmosphere adapted to the lungs alone. There is now no want of evidence to justify the expression of such an opinion without hesitation.

Sixthly, that the indirect injury which irrespirable air produces, by confining invalids at home, is of so serious an amount to the general health and to the spirits, and thence to the lungs themselves, that our measures should embrace, if possible, the highly desirable object of releasing them from a dispiriting confinement, to enjoy exercise in the open air, with their limbs unembarrassed by any apparatus, yet their lungs being supplied, wherever they turn, with just such an atmosphere as we may wish to exhibit to the sensitive membrane.

Seventhly, That, since a heavy load of clothing, however necessary in other respects, is unquestionably oppressive to the skin, tending to disturb its functions, and to produce a kind of partial *cutaneous suffocation*, it is, at least, desirable to consider whether we can by other means than heavy clothing preserve so much of the warmth of the system as shall admit of some portion of the garments being lightened without any the least chilling of the surface\*. This is not, indeed, any direct or necessary part of a treatment of the lungs; but it is of too much value to

---

\* The correctness of this view will not, I conceive, be at all disturbed by a line of treatment lately introduced, it is said with good effect, in certain stages of pulmonary disease, where, under an air-proof waistcoat, the skin over the chest is kept moist, not only by the confined perspiration, but also by a moistened cloth, or sponge, worn all day. If this treatment is as beneficial as I have heard it pronounced, it offers to our view an interesting inquiry. It is plainly a condition of the portion of the skin so treated, the very opposite to that which obtains in a tropical climate, with light clothing under a dry air. In the former case, the perspiration, though apparently increased, is actually diminished; a portion of that which was passing off as insensible, being now detained as sensible perspiration. Perhaps we may view this as a case where a vicarious action is induced in the pulmonary surface within, by the suppression without, leading to a freer exhalation of moisture over the membrane, and consequent partial relief from one prevailing cause of distress I have dwelt so much upon, namely, the exsiccating action of the air. Any such treatment, however, could, I imagine, only act with benefit for a time, and it does not at all militate against the importance of a permanently free action of the skin, and a consequent lightening of heavy clothing, so far as perfect security against cold will permit.

be lost sight of, if it can be commanded as a collateral acquisition.

Eighthly, That with respect to the grand question, namely, the changes to be wrought on the air, our measures must act both upon physical and mechanical principles. The former, to modify the *temperament* of the air; the latter, for separating from it dust, soot, and other particles of solid matter suspended in it. With respect to the first, the *temperament* of the air, we find that one general indication in this climate is to raise its temperature, its coldness being the grand irritant. The next point is to modify its condition in regard to moisture. Even a cold air is often far too dry for a membrane, to which, as has been abundantly shown, evaporation is no comforting process: and however moist the air may be at a low temperature, if we raise it to a summer heat we give it so many degrees of dryness as to disqualify it altogether for the soothing action desired. Hence we must command means by which to add moisture to it; and however injurious damp air is to the lungs when cold, or, again, warm air when not moist, if we combine both agents, warmth and moisture, and *administer them only to the lungs*, we shall find in practice that irritable lungs, in a large majority of cases, rejoice under the soothing influence of air warm and moist to a considerable degree.

It will be readily conceived that any mind upon which the above indications have been deeply impressed by a contemplation of the subject at large of pulmonary distress, must be impelled to an earnest desire to possess the instrumental means for giving effect to them; and it will appear, that of these eight indications, some might be carried out while the body was at rest, and in bed; while to fulfil the whole of them, the body must be free for locomotion, and for exercise out of doors. The former case might be presumed more easy to be dealt with than the latter; and to myself it proved so.

Hence, when impelled by the various considerations which have been detailed throughout these papers, while my attention was directed only to the case of a person in bed, it did not prove very difficult to devise means by which I believe the desirable varieties of

atmosphere might be afforded to the lungs without intermission; also without inconvenience to, or attention on the part of the patient, and without involving the whole body in its operation. It differs, in many respects, from the apparatus, of which I ventured to give an outline while proposing a treatment, akin to the present, for acute diseases in hospital practice; but, as it has not been ever constructed as yet, I am unwilling to occupy the time of the reader by entering into any detail respecting the peculiarities of its construction.

Great, and important, as would, I believe, be the relief afforded by such means to many nightly sufferers, the action of the apparatus would be limited to the night, excepting in the cases of bed-ridden persons. It would therefore, alone, not command the essential requisite of continuous action extended to the day; nor could it offer any of the great, though indirect, benefits certain to follow a release from confinement within doors. Nevertheless the need of atmospheric comfort by many sufferers at night is so urgent that, although they may command, by the aid of means about to be described, a considerable portion of the benefits indicated, I shall not relinquish the hope of reducing, at some future time, to effective operation, the above plan, adapted to the circumstances of a person in bed. It must admit of every desirable variety of temperament being given to the pulmonary atmosphere, while the selection of the choicest in each particular case would rest upon the sagacity and experience of the physician.

I have now to relate the progress of the endeavour to fulfil the whole of the above indications; a result which, if attainable, I felt would be of the greatest importance. Though I cannot, indeed, say it has been within the power of my humble labours to realise the whole to their full extent, and though I have to lament the inability to discern how this point shall be attained, I have to feel thankful that my exertions have not been unavailing, but that a success in the way of useful effect has attended them surpassing very much any anticipations I had ventured to form. I set to work, with the objects to be desired arranged before my mind in the order of their

importance; and in the Respirator is embodied all that I have been able to attain with a due attention to the demands of collateral and unavoidable circumstances.

Though the name of this instrument is well known to the public, and to a considerable extent its capabilities, the latter are by no means all appreciated, even by the many who avail themselves of the more prominent and immediate effects of it; and the profession in general does not yet, by any means, employ all its powers. With respect to its principle and mode of action, many particulars included in them have hitherto received little attention. These facts are attributable to my having offered, neither to the profession nor to the public, any detailed account of the instrument; and scarcely any matter beyond a pamphlet of a few pages, in which, upon the first appearance of the Respirator, the attention of the former was invited to its general objects. From my notes, a few materials have been, at times, abstracted for circulation amongst the public, by the parties to whom the disposal of the Respirator was consigned. I have long felt called on to publish a fuller account, with more carefully arranged details, especially since a large body of interesting facts connected with its action have accumulated, and since its extensive use by the invalid public has given it a notoriety, and interest, which lead to daily inquiries after some publication of a suitable character.

It is not my intention, however, to trespass at any such length on the pages of a professional journal obligingly opened to me; but I may desire to offer a few condensed remarks upon the principle and progress of the invention, and upon its observed action in a few of the more striking cases; since it might be shown that, in the absence of any proper account which would serve to guard against the accident, remarks upon it, altogether erroneous, have found their way even into recent professional works of deserved reputation.

Although I may be allowed to wish, that by more attention to the principles in science concerned, an author would avoid a misapprehension of my labours, I would not here trouble the professional reader upon such grounds; but there are professional and public

reasons which render necessary an endeavour to prevent the occurrence of mistakes of the nature alluded to.

The instance of one class of invalids alone will suffice to point out the importance of caution when writing upon such a subject. There are many thousand persons whose family duties compel them to remain in England, but do not permit them to remain at home, while exposure throughout the winter proves, in a few years, fatal to them. It is a fact, that of these, many hundreds are pursuing their labours from year to year with impunity under the protection of the Respirator. I take here the lowest ground, and leave out of the question those striking cases of gradual recovery under its use. It will here be evident, that to such persons the opinion which led them to place reliance on the instrument in the first instance was of vital importance, for to them the instrument has become of inestimable value; a fact which I need not hesitate to state, since it arises out of an urgent need on their part, which the Respirator happens to meet. Now if the numerous persons who have been recently instructed in the opinion that any roughly constructed article would answer all the purposes of the metallic instrument, should yield to it, and thereby, as a certain consequence, lose all the benefit of the principle, and perish, as many still do, from exposure, whose prejudices prevent their availing themselves of it, the effect would be far more serious, owing to the number misled, than of any incautious medical opinion upon a single case, however erroneous. It may be true, indeed, that the reputation acquired by the instrument will serve as an efficient guard to the invalid public, but it is to be regretted that they should have to owe to their own judgment and experience, protection against a professional opinion tending to mislead them in a serious degree; and it must be obvious that all such mistakes, however inadvertently made, are unfavourable for that growth of public confidence in the profession, so much to be desired, not less for the sake of the public than of the profession, in these days of wide-spread empiricism. Upon these grounds I feel called on to offer to the reader who will favour me with attention, an account of the invention, brief, yet

sufficiently full to supply him with a view of the whole principle and general effect of the Respirator, and thereby save him the trouble of tracing them out himself when an opinion is required of him. The reader has before him the chief indications, in the eight I have enumerated, and also the path through which I was led to become impressed with the importance of them.

Having no idea, for a considerable time, of turning animal heat to account, I felt that I had in vain sought out so great an extent of need, since I had no way of supplying it. I therefore confined my attention for the time to the atmospheric treatment of all the surfaces, the skin and the lungs, by carrying into effect measures I had formerly been led to contrive for giving a right temperament to the atmosphere of dwellings. At this juncture the case of a relation, labouring under pulmonary disease of a fatal amount, renewed in my mind the importance of all those indications pointing to exercise and fresh air out of doors, and a disencumbering of the skin.

In the case of this sufferer, confinement in-doors, from its effect upon other labouring organs and the health generally, exceeded in injury even an exposure to the severest atmosphere out of doors; although the invariable consequence of this was an amount of distress painful to witness, and precipitating the fatal termination of the disease.

Some portable source of warmth and moisture was loudly called for; nor were means for removing, if possible, the smoke and dust of London air to be overlooked; for they actually blacken the sputa coughed up after any considerable exposure.

As may be supposed, the idea of a lamp first suggested itself; but the awkwardness and weight of any such apparatus, especially of a chimney necessary for conducting above the head the noxious products of the combustion, and of additional apparatus for giving moisture to the fresh air for respiration, warmed exterior to the case of the lamp, together with other reasons, caused me at once to reject so cumbrous and troublesome a plan. I have referred to it, because an attempt recently made to introduce an apparatus, in which a lamp is employed, but in a very deleterious manner, has, it is

affirmed, received some professional countenance. Such can only have been given hastily, since the air is poisoned with the products of combustion, and rendered injuriously arid: these, with the general character of the proposal, would have otherwise rendered it unworthy of notice.

I was next led to seek warmth from the body itself; but from the outer surface. A little calculation, however, made it evident that the skin could not at all endure such an abstraction of heat from it, since the natural extrication through thick clothing even, keeps it in so chilly a state as to compel many to burden themselves with coverings, and thus to give rise to the seventh indication.

I now gave up the pursuit until on one occasion, while leading my invalid relation out for exercise, it occurred to me as obvious, that the very chilling of the respiratory passages by cold air was no other than the removal by the air of a quantity of warmth, which, had it been presented to the air previously, would have rendered it abundantly warm; nay, even more warm than enough; so that in each act of respiration, if the air could acquire the warmth one stage earlier, before it touched the pulmonary surfaces instead of afterwards, the object, as to warming it, would be gained. The subject then placed itself in another light; namely, that the heat developed by such invalids was evidently insufficient to meet all the demands from without upon the system. Hence the distress occasioned by that constant abstraction of heat, of which every outgoing breath was robbing the lungs.

The question then arose whether it might not be possible to recover this heat, without any detention of the impure gaseous matter of the breath. If practicable, it was obvious that it must be effected by that movement of heat named conduction; and if by conduction, then manifestly through the instrumentality of metal. But it was doubtful if even the best conducting metal could be made to catch the warmth with the rapidity necessary in so momentary an act—"in a breath." Hence, it appears surprising how any persons rightly informed in the properties of different kinds of matter in relation to heat, and having the right material already before them, should

imagine that any other material than metal would answer the purpose.

Upon commencing to reduce the idea of employing metallic conduction to some practical form, I first thought of letting the warm breath pass out through a number of small tubes, or spaces, formed by metal, which should conduct warmth to cold air entering spaces, around the tubes. Apart from the great inconvenience of its length and bulk, a little further reflection made it obvious that it would be defective altogether in principle. It might answer if inspiration and expiration were performed simultaneously, the one forming a continuous counter-current with the other; but it was wholly unsuited to the actual case of respiration, in which the movement of the currents is alternate. I think it right to mention this defective plan, since it has more than once been proposed as an improvement.

In any case of continuous counter-currents, the conducting metal has to perform the duty only of a road for the travelling of the heat across from the one current to the other; but in the case in question a metallic storehouse was evidently wanted, into which the warmth might be safely and quickly deposited by the outgoing current, there to lie until taken up by the fresh entering current.

It was next plain that, in order to conduct off the warmth with the necessary rapidity from every portion of the gaseous current, it would have to be acted upon by metallic contact in every part; for which purpose the breath must be subdivided, or split into the greatest number of currents. This might be effected by a multitude of thin short plates of metal. A A, &c. fig. 1, sets parallel to each other, and

FIG. I.

edgeways to the current C C, or D D, the plains of these plates lying in the direction of the current. These plates

would receive warmth from the outgoing current—say D D. They would, if properly encased in some non-conducting material, store it up to be received by the entering cold current C C, and thus a respirator would be formed. This was the first idea I formed of a kind at all proper. It is curious that this also has been proposed to me as a superior modification of the Respirator. Though incomparably better than the other, its action would be very imperfect, as the reader will readily perceive. Since there is a continuity of metal in every plate, all the way from A to B, it is plain that the point A, next the mouth, could never be materially warmer than the outer point B; for any excess of warmth would rush from the former to the latter. Whatever were the relative capacities for heat of the metal, and the breath, with such a construction, the one could only give half of its warmth to the other. Thus when the inner half of each plate towards A had taken up all the warmth it could from the outgoing currents, the outer half towards B would get no more from it; for the metallic continuity would ensure its being nearly at the same temperature with the inner. The process would be confined to one step of conduction; a deep one indeed, but a single step only. If, then, the capacities of the metal and breath were the same, but one half of the warmth could be taken by the metal, supposing the conduction absolutely perfect, which of course is far from the case with any metal; or any means we have of applying it. Again, the entering cold current could only receive, according to the utmost which theory would give, one half of the warmth stored up in the metal, that is, one half of one half, or a quarter of the warmth which the breath had brought from the lungs. After a long repetition of the process, the quantity would verge nearer to one half of the whole warmth, for a reason which I will not consume space in explaining; but it could never amount to it, and in practice it would be much less.

Hence the necessity of a further insight into the question before we arrive at that perfection short of which no philosophic mind will be contented to rest. The reader will by this time have anticipated the necessity of more than

one step or stage of conduction. The warm breath, after one set of metallic conductors has taken from it all the warmth it can, must be presented to the action of another set of a lower temperature; for if it were of the same, it could, of course, take no heat from the breath. But even two conducting layers do not suffice. In practice from six to twelve, or fourteen, are required, according to the temperature we desire to give to the incoming air; and for certain reasons it is desirable that each layer should be double, the total number of layers being twice the above. Again, a little space is required between each double layer, amounting to the fortieth of an inch; and as the whole are to be compressed into about a quarter of an inch, each layer must occupy the smallest possible space. Now referring to the above diagram, it will be evident that if we divide the plates A, A, &c. (which are almost geometrical planes, having length and breadth without

thickness), to a great extent crossways, we shall convert them into lines, which have length with scarcely any breadth or thickness; in short, into extremely fine wires. It was thus that I was led to the selection of wire, since one principle required extreme subdivision from front to back, while another demanded the same from side to side. The two, therefore, reduced the conducting material to merely upright lines.

To support such fine wires, and keep them in a state of tension, I employed delicate frames of metal, like that of a window. They had to be made in a peculiar manner, and to every horizontal bar the wires were soldered: each frame carrying two surfaces of wire. The frames are kept apart by small studs, which, touching them only in a few points, and being of a material which conducts heat badly, have no effect in disturbing the independent temperature of each layer. This arrangement is seen in fig. 2, which re-

presents a Respirator with the investing leather removed where it covers the metal work. A A are wired frames, and B B the intervening studs. The gradative action of the instrument will at once appear on an inspection of the columns of figures on either side. That on the left hand represents the temperature of the several layers, just after an act of expiration has warmed them.

The innermost one has been raised to 80° by the breath, which, reduced by this loss of heat nearly to that temperature, could give no more warmth to it. But the next layer was cooler, and could receive warmth, until, rising to 76°, it again could gain no more from the air. In the same way the third, and all the successive layers, were quali-

fied by their progressively lower temperatures to draw warmth from the air, in their turn, after each preceding layer ceased to act, until the air upon its escape was reduced below 50°, having raised the outer plate to 44°.

The right hand column serves to represent the progressive rise of the entering air from the freezing point, until it reaches in this a *medium* respirator, the temperature of 68°—a grade far above that of the outer layers, which had given it when cold, the first stages, or as it were the foundation, of its now accumulated warmth. In the respirator of *highest* power, the entering current can thus be brought up in a moment from the freezing point to the usual summer heat of Bengal. Such is

the importance of this gradative principle for giving effect to the *storehouse* or *depositive* conduction, required to suit the *alternate movement* of the currents in respiration.

[To be continued.]

---

OBSERVATIONS  
ON THE  
STATISTICS OF PHTHISIS,  
AND ON THE INFLUENCE OF CLIMATE AND  
OCCUPATION IN THE PRODUCTION OF  
THAT DISEASE.\*

"La médecine ne serait ni une science ni un art, si elle n'était pas fondée sur de nombreuses observations"—*Poisson, Recherches sur la probabilité des jugemens.*

[Continued from p. 178.]

THAT any disease of the respiratory organs must be affected by the nature of the climate enjoyed by the patient, is a supposition so natural and obvious, that we find it supported by the authority and practice of the earliest writers on the theory of medicine.

Neither are theories and hypotheses on this point wanted at the present day; nor is the importance of the subject less felt by modern practitioners in our own times. Indeed, the contrary is the case, and many efforts have of late years been made to solve the problem of the effect of climate on pulmonary diseases; but, whilst the mass of observations is so small as it yet is, and the observations themselves are recorded with so little exactness and precision as they for the most are, but few exact and general conclusions of importance can be drawn from them. Still we may make a first approximation to the truth, and by the help of numerical statements give some degree of exactness to theories which, from the vagueness and indeterminate meaning of the terms employed in the relation of the facts on which they are founded, are otherwise necessarily doubtful.

To obtain a tolerable notion of the nature and extent of the influence which may possibly be exerted by climate in producing or increasing a tendency to disease of the respiratory organs, we must pay attention to the functions which the lungs have to perform, and then consider the effect which any change or variation, either of the at-

mosphere or of climate, properly so called, which is met with in this or other countries, can have in assisting or hindering the lungs in the performance of these functions.

Wherever numerical statements are at our command, we shall of course avail ourselves of them; but, unfortunately, we must sometimes content ourselves with merely the statements of various writers as to the freedom from, or frequency of, phthisis in particular places. On assertions like these, unless founded on great experience, too much reliance must not be placed; for, as has been well observed by Gavanet, "the *sometimes* of the cautious is the *often* of the sanguine, the *always* of the empiric, and the *never* of the sceptic; but the numbers 1, 10, 100, 1000, have but one meaning for all mankind."

The difference in the climate of two different places must be included under some or all of the following heads:—the chemical constitution of the atmosphere, the mean pressure and temperature of the air, and its hygrometric state. There is also to be taken into account the extent of the variations from the mean temperature and pressure common at each place, the rapidity with which these changes are effected, and the frequency of their occurrence.

The chemical composition of the atmosphere is so constant and uniform, that it is not probable that any variation in the proportion of the constituents of air is sufficiently great to produce or affect disease of the lungs: in certain cases, of course, the lungs are affected by the injurious exhalations or vapours produced in various operations in manufactories; but this belongs to a different head of our subject—that of occupation rather than climate; and it does not appear that the difference (if any there be) in the chemical constitution of the atmosphere, at different places in this and most other countries, has any great effect on the frequency or fatality of phthisis.

The introduction of extraneous substances into the lungs is an evil to which in general only particular classes of operatives are exposed; and the only circumstance of this nature which affects all classes equally, is the inhalation of dust. I may possibly have occasion hereafter to illustrate the destructive effects of inhaling any solid substances, as exemplified in the health of the workmen

---

\* Communicated by the author.

employed in various manufactures, but I shall now merely refer my readers to the treatise of Thackrah, and an interesting report by Villermé, published in the *Annales d'Hygiène*, on the health of persons engaged in the cotton manufacture. The operation of beating cotton, from the great dust raised in the process, increases, according to both of these authors, the mortality from phthisis; and it is not probable that the irritating and angular particles of dust are less injurious to the lungs.

Dr. Hennen, in his very valuable and interesting posthumous work\*, has some remarks in connection with this subject in that part of his book relating to the climate of Malta, and the sanatory state of the troops stationed in that island.

The climate of Malta† is dry, and the temperature neither very variable nor low: from December till February the rain falls with tropical violence; but from that period till August not a drop falls, and the sky is generally cloudless. The island itself (appears, from its geological formation, there being neither rivers, lakes, bogs, nor morasses in it), to be favourable to health, and yet the mortality from phthisis, though inferior to the mortality from that disease occurring in England, is nevertheless much higher than might have been anticipated. Hennen affirms that the disease is very common; and according to Major Tulloch, the ratio in each 1000 troops attacked annually by phthisis is—

In the United Kingdom . . . 6.6

In Malta . . . . . 6.4

Amongst the civil and native population of Malta, the deaths from consumption, from the year 1822 to 1831 inclusive, amounted to 4149, the average population during this period being 100,270, and the aggregate population 1,303,517. In the table below is given, in the first column, the number of deaths from consumption in each year among the civil and native population of the island; in the third, the calculated amount of the population at each period; and in the fourth, the number of deaths annually from phthisis in each 100 persons living. We may

\* The Medical Topography of the Mediterranean, p. 446.

† In 1823, hygrometer 87 max., 30 min., and 58½ med.; and the temperature during six years was 90 max., 46 min., and 63 med.—Hennen, p. 431.

premise, that the number of deaths assigned to phthisis is most probably rather above than below the truth:—

*From Phthisis and Consumption.*

Deaths.	Year.	Estimated population.	Deaths per cent.
298	1822	95,484	·312
267	1823	96,943	·278
206	1824	96,404	·214
244	1825	97,627	·249
245	1826	98,739	·248
286	1827	99,549	·287
311	1828	100,949	·308
297	1829	101,776	·292
393	1830	101,962	·385
375	1831	102,839	·363
331	1832	104,263	·317
509	1833	104,056	·489
387	1834	103,926	·372
			Mean .316

In 1833, it will be seen from the above table, that the mortality from the disease was much above the average, being double the amount in the earlier years. The weather in the early part of that year was such as is usually experienced; but in the latter part of the year it was much more variable than usual; dry and moist, warm and cold weather, following in rapid succession, with occasional heavy rains\*.

Hennen attributes, and it appears to me with considerable justice, a large amount of the deaths from pulmonary diseases to the extreme dustiness of the climate, and the consequent introduction of irritating particles into the lungs.

His description† of the climate of Malta in this respect is very striking. "From the action of the winds," he says, "and the dryness of the atmosphere, taken in connection with the nature of the soil, there results a phenomenon which affects the climate of Malta in a manner strikingly cognizable to the senses, and which I am convinced is productive of considerable influence on some of our diseases. I allude to the volumes of impalpable dust which float about in the atmosphere, especially in summer and autumn. Every wind which blows over the exsiccated surface of the island takes up this dust, which is so fine, so light, and so pene-

\* Tulloch: Reports on the Sickness and Invaliding of Troops in Malta.

† Ibid. p. 446.

trating, that the closest door does not offer an effectual barrier to its entrance; the eyes and face are clogged up with it; it is forced through the clothes, and all parts of the skin are covered with it; and so subtle is its nature, that it occasionally finds its way into the works of the best cased-watch, even in the pocket. When a damp wind blows, or when the dews and fogs are heavy, this floating dust is moistened, its particles coalesce, and it is precipitated in the form of drops of a very fine mud. We frequently see the plants in a morning covered with this precipitate."

The influence of dust in increasing the frequency of pulmonary diseases, is also well illustrated by the observations made by Bremner in his account of Odessa\*.

Setting aside, then, the consideration of the changes which sometimes possibly occur in the chemical constitution of the atmosphere, and which we may afterwards notice when discussing the climate of, and mortality in, cities as compared with that of the country, and the effect of particular occupations on the health of the artizans engaged in them, there remains to be noticed only the effects which the variations in temperature, dryness, and pressure of the atmosphere, have in increasing the frequency of diseases of the lungs.

That the density and pressure of the atmosphere must have some considerable influence on the lungs can scarcely be doubted; for, the cavity of the chest always remaining the same, the greater the density of the air the greater will be the weight of the air introduced into the lungs at each respiration, and the system consuming the same weight of oxygen, the fewer will be the number of inspirations and expirations in a given time: but the point to which I shall now principally direct the attention of my readers is that of the influence of moisture; and this I shall do principally because there are no sufficient data respecting any connexion between the frequency of phthisis and the pressure of the atmosphere, and on this account it will be useless to enter on the subject.

So far as is known on the subject, the purpose of respiration appears to be the removal of the carbonic acid contained in the venous blood, and the

absorption of a somewhat greater volume of oxygen from the air, and, in addition, either the absorption or exhalation of nitrogen, this gas being sometimes absorbed from the atmosphere, and sometimes exhaled from the blood. These are the principal chemical changes effected in respiration which press themselves more immediately on our notice; but there is another office of the lungs to the due performance of which I am disposed to attach the highest importance, but which is, in general, comparatively disregarded—I mean the exhalation of the aqueous vapour or steam from the blood during its passage through the lungs. Considering this exhalation of the vapour of water only as the means of removing an unnecessary or injurious quantity of water from the blood, the continuance of such a function must be, considering the large quantity that is thus thrown off, of a high degree of importance; but when we consider the great loss of heat which the blood must undergo in converting that portion of water which is separated from it into steam, the separation of this portion of water from the blood appears in a still more important light.

Our illustrious countryman, Dalton, has shown\* that in one particular individual, taking daily into his stomach 53 ounces of fluid, the whole evaporation from the lungs and skin together amounted to 27½ oz. in the 24 hours, of which quantity only 6½ oz. were given off from the skin, the remaining 20½ oz. or 1·275 pounds, avoirdupois, being thrown off from the lungs. To form a more distinct idea of the amount of heat required to throw off this quantity of water from the human lungs, let us assume the latent heat of steam to be, as was proved by the experiments of the celebrated Watt, about 950°; then the quantity of heat required to convert the above weight of water into steam would be sufficient to raise the temperature of nearly eight pounds of water from the freezing to the boiling point. It is thus evident that an immense quantity of heat is drawn from the blood and the system generally by the continual evaporation going on in the lungs.

But, important as the perfect exercise of the lungs would, even on this account alone, appear to be, it is pro-

\* Excursions in Russia, vol. ii. p. 474.

\* Trans. Phil. Soc. Manchester, vol. v. p. 315.

bable that, if viewed simply in this manner, we should greatly underrate the importance of this phenomenon in the economy of human life. A distinguished living chemist and physiologist\* assigns a highly important office to the process of evaporation from the lungs, conceiving that by means of this evaporation an important chemical change is effected. "With respect," he says, "to the aqueous vapour thrown off from the lungs, we have every reason to believe that much of this vapour is derived from the chyle in its passage through the lungs; and that by such separation of water the weak and delicate albumen of the chyle is converted into the strong and perfect albumen of the blood." Thus, considering the matter *à priori*, and without reference to any known facts on the subject, there scarcely can be a doubt that the continuance of this evaporation from the lungs, or indeed the extent to which it takes place, is a point which is of the highest importance to the healthy condition of the human frame, and that the due performance of this process, and the prevention or partial suspension of it by peculiarities of climate or other external circumstances, must exercise an important influence, either for good or for evil, on the healthy condition of the lungs, as being the organs immediately affected by the continuance or suspension of this function.

Now this office of the lungs will, of course, be affected both by the temperature and pressure of the atmosphere, as also, and principally, by the quantity of moisture present at the time in the air; the pressure of the atmosphere diminishing only the rate at which the water can be evaporated. The quantity of moisture which can be thrown off from the lungs will vary accordingly, and be proportional to the temperature of the blood in the lungs, and the difference between the elastic force of vapour at that temperature, and the elastic force of the vapour already existing in the atmosphere. Suppose, for example, a climate possessing an ordinary temperature of  $100^{\circ}$ , and the atmosphere of such place to be also saturated with moisture; then, as the temperature of the body is wholly uninfluenced by the temperature of the atmosphere, and is precisely the same

at the equator as it is at the poles, the blood, supposing it to be of no higher a temperature than  $100^{\circ}$ , would be unable to throw off any of the water which, in a less humid climate, would be evaporated from the lungs. Hence, if we may be allowed to suppose that the discontinuance of the evaporation from the blood is one of the causes which tend to induce phthisis—and there certainly appears to me some degree of probability that such is the case, as the facts which I shall presently bring before my readers will, I think, show—we might expect that in tropical countries, enjoying a very high temperature, and where the atmosphere is nearly saturated with moisture, there phthisis would be found to be very prevalent: in some countries situated near the equator, at least in the West Indies, this appears to be the case, as is demonstrated by Major Tulloch's Reports on the Medical Statistics of the British Army, and to which reports I shall presently have occasion to refer more particularly.

We all know, from experience, the disagreeable, and sometimes even distressing, feeling, caused, as I believe, by the partial suspension of this office of the lungs in wet and warm weather, and which we term closeness; and we cannot but suppose that the entire, or nearly entire, suppression of the steam usually thrown off from the lungs, must be, in some manner or another, highly pernicious to the system.

As to the influence of a moist climate on phthisis, it has been generally considered as rather prophylactic against that disease than injurious; and this opinion is one which has been entertained by writers of the greatest talent and the highest authority. Thus M. Lombard\*, who has attempted to represent, numerically, the influence of various circumstances in increasing or checking the predisposition to phthisis, places the preservative influence of exposure to aqueous vapour at 0.053, whilst he considers the injurious effect of dry air in increasing the tendency to phthisis, as represented by 0.127. Many earlier writers who held this opinion might be quoted; and this hypothesis is also supported by one of the most modern, and certainly the highest au-

\* Prout, Bridgewater Treatise, p. 530.

\* See Quetelet *sur l'Homme*, where an analysis of Lombard's paper is given.

thority on the subject—I mean M. Louis.

To attack an opinion thus supported by the concurrent testimony of almost every medical writer for a long period, including those of the highest eminence, and the most distinguished for their philosophical views, certainly requires no little hardihood; but I think the many facts, accurately stated, and which may be firmly relied on, that may now be found in the elaborate reports of the Registrar-General and Major Tulloch, are sufficient to show that this opinion requires reviewing before we can accede to its general truth: and though neither my time nor space will allow me to investigate these and other documents so closely as I could wish, yet I think some of the facts which I shall draw from them will tend, so far as they go, to prove that the old and favourite rule, that a mild, equable, and moist climate, is always the least favourable to the development of phthisis, is not in every case correct.

But before discussing the question of the effect of humidity of climate on the frequency of phthisis, it will be desirable to state the following proposition, and to illustrate it by some examples. The preliminary proposition that we wish to establish is the following:—The effect of variability of climate as to temperature, and the extremes of heat and cold to which any country is subject, have no perceptible influence in increasing the amount of mortality from phthisis. This, again, is an opinion in direct opposition to that of most authorities on this subject. Young\*, for example, affirms that “in those climates which are constantly very hot or very cold, the disease, in its genuine form, is but little known.” This assertion, I admit, certainly does hold good in some cases; but I think that this arises from a very different reason than the mere uniformity of temperature to which the human body is subjected; and certainly the assertion of Young is far from holding good generally. As an example, however, of the occasional truth of his remark, we shall now say a few words on the climate of, and prevalence of phthisis in, Egypt.

[To be continued.]

CICERO.

### THE ANATOMY BILL.

THE legislative regulations with regard to anatomical schools, have again been brought under our consideration, in a petition presented to the House of Lords, the other evening, by Earl Stanhope, having for its author Mr. Roberts, and for its burden, complaints against the conduct of the Commissioners appointed to inquire into the working of the Anatomy Act.

It must be confessed on all hands, that by directing the attention of the public to the details of this Act, and making so prominent a display of its deficiencies, those feelings of antipathy to post-mortem examinations, which, existing in some degree in the minds of most persons, are in many sufficiently strong to overcome the better dictates of reason and education, are excited—the prejudices against dissecting-rooms are strengthened—and the difficulties in the way of obtaining a sufficient supply of bodies are increased. Indeed, so little benefit is likely to be the result of public investigation into this system, and so much disadvantage is liable to follow from it, that nothing but an urgent necessity can justify any one in making it the topic of parliamentary discussion. What, then, are we to say to the interference of Mr. Roberts on the present occasion,—an interference not only unnecessary but actually injurious, directly tending, as it undoubtedly does, still further to embarrass the present scheme of obtaining bodies for dissection? Earl Stanhope mentions him as a gentleman, whose discoveries with reference to a mode of preserving bodies from decomposition had been of the

greatest advantage to anatomical science, and therefore appears to consider a petition coming from him as one peculiarly deserving of attention. But on the contrary, we are not aware that any advantage whatever has been the result of this discovery, so loudly and extensively lauded by its author. We have before shewn, that these plans of arresting putrefaction are not applicable to the ordinary purposes of anatomical investigation in the schools; and perhaps no better evidence of the inutility of this one in particular, as well as of the real desire which Mr. Roberts feels to promote the advancement of anatomical science, can be found, than that which is to be derived from a consideration of the means he has adopted to obtain notoriety, and bring about its more general employment. The first obstacle to this, being of course, a regular and sufficient supply of fresh subjects, his great endeavour is to interfere in every possible manner with the efficient working of the Anatomy Bill. On this principle alone can we explain the fact that, not content with various other proceedings to which we have formerly alluded, he every now and then attempts to provoke the indignation of the public, by petitions to Parliament against the grievances and abuses of the Anatomy Act. Screening the real object of bringing his own "discovery" into use, he comes forward as the exposé of the "Helpless Condition of the Workhouse Pauper." We have already on previous occasions adverted to the mischievous interference of this person, and regret that we should again have such reason to express our disapprobation of his measures; but they are so evidently injurious to that which he professes to be his great object—namely, the promotion of anatomical knowledge, that we cannot refrain from expressing our strong opinion of them. We do not profess to

esteem the Anatomy Act as perfect, or to uphold Dr. Somerville in all his proceedings; on the contrary, we have often pointed out the defects of the one, and exposed the negligences of the other. At the same time, we do think that this act, if properly carried out, is calculated in great measure to effect its object; and we must also acknowledge with pleasure that greater diligence has of late been evinced by those gentlemen whose duty it is to superintend its operation: in consequence of which increased energy, its benefits have been more conspicuous, and during the last two seasons the dissecting-rooms in the metropolis have been better supplied than they previously were. In the last winter, it is true, there has been some falling off, as compared with the preceding, but this may be attributed to accidental circumstances, which it is not in the power of the Inspector to control.

One of the complaints urged by Mr. Roberts in his petition is, "that the dissected bodies are not granted the proper rites of burial in consecrated ground; by which omission that clause of the Act has been violated which provides, 'that after a body has undergone dissection, it shall be decently interred in consecrated ground, and that a certificate of the interment shall be transmitted to the Inspector of the district, within six weeks after the day on which such body was received by the Professor of Anatomy.' The cause of Religion has been insulted, the best and strongest feelings of the poor have been outraged, and ecclesiastical law has been contravened." In the excellence of this provision of the Act we most willingly agree. Even if we exclude the claims of morality and religion, it is beneficial, inasmuch as, by securing the decent interment of subjects, it removes one ground of objection, existing in the minds of many persons, against the

dissecting rooms, and thereby facilitates the means of supplying them. But we are by no means prepared to admit, with Mr. Roberts, that the provision is violated in the manner stated by him. The two principal sources from which the subjects in the metropolis are obtained are, the large hospitals and the workhouses. The bodies derived from the former, having undergone dissection, are interred in the burial ground connected with the hospital; while those received from the workhouses, which form the greater number, are returned to those houses, and obtain the rites of burial in common with the undissected bodies interred at the parish cost. All are buried in consecrated ground, and with the same funeral rites. If, therefore, any complaints are to be raised against the place and manner in which these ceremonies are performed, they must be made against the *whole* system as carried on under parish authorities. It is evidently neither fair nor just to level the charge against the anatomical inspectors, or to make the present system of burial the ground for loading scandal upon the schools of anatomy, and exciting the dread of the poor. To suppose that every portion of a body, divided into so many fragments as one that has undergone anatomical examination must necessarily be, can be recollected exactly and accurately, would be absurd: we may, however, state on good grounds that, as far as possible, the whole is returned for interment. We should be led to a different opinion, and imagine that a great taste for anatomical putrescence exists in our schools, from the statement of Mr. Roberts, in which he affirms, that he has seen many hundred weights of human flesh thrown into heaps, and allowed to rot. He does not inform us in what part of the United Kingdom this exhibition may be witnessed, the bare relation of it being deemed by him

sufficient to excite the sympathies of the credulous, and increase the disgust too often felt at the mention of the subject.

The petitioner further states, that from his own observation, he has found the anticipation of dissection to be a source of deep anxiety and grief to a large number of the workhouse-poor. In reference to this, we would ask, who have been the means of spreading abroad the fancied horrors of dissection? and who have most contributed to excite this alarm and anxiety in the minds of the paupers? Surely those who are perpetually representing anatomical investigation to them in its most formidable colours, and, under a pretended zeal for humanity, torment the living with apprehensions respecting the fate of their bodies after death, must bear the onus of this charge. It is well known that Mr. Roberts has laboured hard to terrify the poor—to excite in them horror at the very name of an anatomical school; in fact, to foster those very feelings which he now urges as an argument against the present system.

We not unfrequently hear mention of the “helplessness of the poor,” and the “inability of the friendless pauper to avoid post-mortem examinations;” and they are adduced as hardships in the petition before us; being brought forward in such a manner as to induce persons unacquainted with the subject to imagine that some compulsory measures are had recourse to, and that bodies are removed for anatomical purposes without the consent of relations, or the previously-expressed wish of the party himself—a conclusion most unjust, and in direct opposition to the truth; the fact being, that the poor have the power to preserve themselves, or their relatives, from dissection, by simply expressing an objection to it. It is well known that the only

subjects of examination are the bodies of those persons whose friends make no opposition to this appropriation of them; and also those which remain for a certain length of time after death, unclaimed by any relatives. Could a better provision than this have been made? The common dictates of humanity are obeyed, and the feelings of the poor are respected. Why, then, is it exclaimed against? why is the clamour raised that the pauper is unable to protect himself? The reason will best be found in the interested motives of those who urge these unfounded complaints.

That the Anatomical Bill may produce the good effects which it proposes, and which are expected of it—that is to say, a diminution of the antipathy to dissection, and also the more abundant supply of subjects—it is essential that it be allowed to work on in quietude. The public excitement upon such a question can only do harm; and we esteem it one of the excellencies of the administration, with regard to it, that the minor alterations which have been required, have, from time to time, been effected by the direction of the Secretary of State, without making a prominent and useless display of each. We cannot but suspect that it is these considerations which induce Mr. Roberts to bring the subject forward for discussion in Parliament, it would be useless to expect him to remain quiet while interest moves him in the opposite direction. We would, however, urge upon others, who may have less concern in its publicity, the necessity of discountenancing the needless appeals made upon this question, and hope that the management of the dissecting-rooms may be left in the hands of those persons, who, being practically conversant with the best means of providing for them, are most likely to avoid mistakes, and ensure the benefit of the community. The subject itself, combining in

its nature much that is loathsome and disgusting in the eyes of the world, is capable of being placed in a still more prejudicial light by the exaggerated assertions of any one who chooses to make this his endeavour. There are very few persons, even of those occupying high stations in society, and possessed of good education, who can resist these prejudices altogether, and who can therefore be expected to form an unbiassed opinion upon the subject, when thus presented to their notice, and painted in its darkest colours. For this reason, if for no other, it is to be wished that those who are not fully conversant with its bearings would turn a deaf ear to the rumours which interested persons are constantly spreading abroad.

#### BUST OF SIR ASTLEY COOPER.

THIS work has been raised to the memory of this distinguished surgeon by his pupils, at a cost of 400 guineas, and was placed in the Anatomical Theatre on Saturday, May 7, on the occasion of the annual distribution of prizes. The bust is by Mr. Towne; and it was much admired both as a work of art, and also on account of its being an excellent likeness of the eminent man to whose memory it is raised. It is mounted on a pedestal of white marble, five feet in height, and embellished with a fine bas relief, and has the following inscription:—

“Astley Paston Cooper. Alumni grato animo hoc marmor posuere. 1841.”

#### SPECIAL REPORT

OF THE

#### COMMITTEE APPOINTED BY THE PROVINCIAL MEDICAL AND SUR- GICAL ASSOCIATION,

*To watch the further progress of the Question of Poor-law Medical Relief, and to suggest to Council, from time to time, such measures as may appear to them necessary to meet circumstances as they arise.*

Dated the 30th of April, 1842.

YOUR Committee, at the request of the central council, have perused and carefully considered the *General Medical Regulations*, and the *explanatory circular* to the Boards

of Guardians, recently issued by the Poor-law commissioners, and recommended to the medical profession by the President of the Royal College of Surgeons.

In submitting to the council the result of their examination of these documents, your Committee would express their satisfaction at perceiving that the strenuous efforts of the medical associations to obtain an amended administration of medical relief for the poor (efforts persevered in under very discouraging circumstances), have at length proved not altogether fruitless.

These exertions may have been censured by some as factions, and by others considered unnecessary or useless; but the beneficial results, at present only partially manifest, will silence numerous objectors, and should encourage the association to a judicious continuance of well-directed endeavours to secure a complete and decisive reformation of the system.

The several improvements directed by the Poor-law commissioners are arranged in the following order.

First, "Tenders for Medical Attendance" (Articles 1 and 2).

Your Committee congratulate the association, and the profession at large, on the abolition of that most obnoxious form of "tender" in which the medical candidate names the sum for which he is ready to undertake the office. It is, however, a matter for unqualified regret that the commissioners still leave the guardians at liberty to fix the price of medical duties without reference to any fixed scale or acknowledged principle of computation.

Secondly, "The Qualification of Medical Officers" (Articles 3, 4, and 5).

Your Committee observe that qualifications in both medicine and surgery will, for the future, be required of candidates for Union appointments. The profession have long contended for the adoption of a similar measure; but the value of the present regulation is much impaired by its exclusiveness, and its obvious tendency to confer an undue advantage on the London College of Surgeons.

Your Committee, however, feel the less anxiety on this point, as it appears more than probable that the measure of medical reform, promised by Government, will satisfactorily adjust the qualification of all medical men in public employment; and thus, in effect, set aside the Commissioner's propositions.

Thirdly, The regulations relative to the maximum area and population of medical districts (Articles 6, 7, 8, and 9) are, in their present state, open to objection; yet their introduction confirms the correctness of the assertion so repeatedly made by your Committee (and more than once denied by

the commissioners\*), that *it is both possible and expedient to establish, by direct enactment*, maximum limits to the population, if not to the area, of medical districts.

The limiting of population to 15,000 in large towns, is a decided improvement upon existing arrangements; but throughout the country, and in the great majority of Unions, this limit will be attended with but little advantage.

Again, the limiting of the area to 15,000 acres will by no means adequately reduce the extent of districts in populous localities, whilst it will be found impracticable, not only in Wales, where the Commissioners do not propose to enforce the rule, but also in several English Unions where the population is widely scattered.

Your Committee have founded all their recommendations on this principle,—that in proportion as the population of the locality is more scattered, so the number of inhabitants included in a medical district should be less. Such a proposition, which avoids the difficulty of fixing a positive limit to the area of thinly populated districts, was embodied in Mr. Serjeant Talfourd's clauses, and has been universally approved of by the profession. Had it been adopted by the Commissioners, it would probably have been unnecessary to provide for any exceptions to the rule. From extended inquiries, your Committee are assured that 4,000, in any part of England and Wales, might be provided with a duly qualified district surgeon, residing within an accessible distance.

Fourthly, Articles 10, 11, 12, and 13, fixing the remuneration for certain operations, accidents, midwifery cases, form another concession to the just demands of the profession: nevertheless, it will be found frequently very difficult to carry into execution the unreasonable provision for a consultation *at the cost of the medical officer*, except in those instances where there is a partner or qualified assistant, whose gratuitous services he may command.

Fifthly, Articles 14 and 15, providing "*substitutes for medical officers*," appear to your Committee unexceptionable, and if rigidly enforced will effect a marked improvement on existing practices.

Sixthly, "The mode of obtaining relief by permanent paupers" (determined by Articles 16, 17, 18, and 19), is another approximation to the propositions of the medical profession.

As the preparation of medical pauper lists is made imperative on every Board of Guardians, it will obviously lead to a more definite and satisfactory method of calculating the salaries of medical officers.

\* See their Report, December 31st, 1839, p. 45; and 7th annual Report, section 20.

Seventhly, The regulation relating to the "continuance in office of medical officers" (Article 20), is intended to establish an important principle, and is calculated to check some of the abuses of the present system; but your Committee doubt whether medical officers will receive either due protection or just consideration so long as they are amenable solely to non-professional authorities, or while their continuance in office depends on the pleasure of parties who are necessarily incompetent to judge respecting the correct performance of medical duties.

It appears, both from the 20th and previous articles, that the Commissioners still intend to permit the practice of *contracting* for medical services.

Your Committee feel strongly the necessity of abolishing this practice.

The appointment of Union Surgeon need not require the execution of any *contract*; nor can previous custom be admitted as a sufficient reason for compelling members of the medical profession to submit to an indignity which is not required of the clergy in their appointment to the office of *Work-house Chaplain*.

The preceding remarks are intended to show the existence of some serious imperfections in the New Poor-Law Regulations; yet, on the whole, they constitute an amendment of the present system, and contain within themselves the germs of future improvement.

It is worthy of observation, that the period of the year at which the regulations are issued virtually precludes their adoption by the great majority of the Boards of Guardians until March 1843. They are, however, circulated throughout the medical profession before the government bill for amending the new Poor-Law has been submitted to Parliament. The object of the Commissioners' in selecting this particular occasion for the announcement of their amendments can scarcely fail to be rightly understood and properly appreciated. If, in consequence of the promulgation of this "general order," the Poor-Law question should be settled by Parliament without any provision for the regulation of medical relief, it will remain to be seen whether the amendments now directed will be strictly and impartially enforced, or whether the Boards of Guardians will be allowed to postpone their adoption at pleasure, or to take improper advantage of the numerous exceptions and relaxations provided by the "order" itself.

The amount of benefit to be derived from the new code will greatly depend on the vigilance of the profession in general, of the colleges and associations in particular, and especially of the several weekly medical

journals, which have so ably and successfully co-operated in the attainment of an improved administration of medical relief.

The main defect in these regulations is that noticed under the first head, namely, the absence of any specific directions respecting the amount of medical salaries, or the method of computing them.

Whether or not this omission may arise, as has been suggested, from a want of power on the part of the Commissioners to establish a principle, or define certain rates of remuneration, is a question of law, on which it would not become your Committee to pronounce an opinion; but they do not hesitate to state their conviction, that so long as the estimate of medical services is allowed to depend on the varying and arbitrary decision of different Boards of Guardians, the profession should continue to appeal to the legislature for the enactment of certain limits (or at least a minimum limit) to the remuneration of Union medical officers, so that due protection may be afforded to the interests of the rate-payers, of the sick poor, and of the medical profession.

The principle which the Commissioners have uniformly sanctioned, and continue to recommend, is to combine a salary calculated on the number of *regular* paupers, with a payment per case for others, both of which modes of payment are perfectly compatible with the recommendation of the Parliamentary Committee, that medical relief should be a parochial, and not a Union charge.

The Commissioners "remark incidentally that unless a system of payment per case is adopted," the recommendation referred to "cannot be carried into effect."

This remark is likely to lead to a very erroneous conclusion. The fact is, that there are other systems of remuneration equally compatible with separate parochial charges.

It is obvious that an average payment per head for the several paupers on the list (the fixed salary) may as readily be charged to their respective parishes as a payment per case for other poor persons.

To carry into effect the above recommendation of the Parliamentary Committee, and to secure a constant attention to the diminution of medical districts, a point imperfectly provided for by the Commissioners' present regulations, your committee are still of opinion that the remuneration for distance or area should constitute a distinct item in the medical salary; that, in every district, it should be separated from the other (constant) items, namely, medicines and medical attendance within a mile of the surgeon's residence; and that it should be charged only on those pauper tickets or cases of illness, or to those parishes or united hamlets, which may be more than one mile distant from the surgeon's residence.

In the clauses D and E, lately published by the Association\*, and submitted to government, the charge for distance was calculated not on individual cases or paupers, but for entire parishes. The distance was proposed to be measured to the nearest point of the parish; and a charge added for its area. It was also suggested† that if the latter charge were omitted, the mean distance of the inhabitants of a parish, or of united hamlets, should be estimated, or some central point taken instead of the nearest boundary.

Your committee consider it a matter of comparative indifference whether the charge for distance be made on parishes or on individual paupers. The "pauper ticket" for the permanent class, and the "order" for the casual poor, would afford an opportunity to the relieving-officer to name the distance of the patient from the medical officer, and would thus enable the clerk of the Union readily to determine the charge for mileage on account of each parish in the district.

The rates of remuneration‡ should not fall below the minimum rates specified in the clauses D and E before referred to.

Your committee are firmly convinced that if the medical salaries were equitably regulated, and a separate charge at the rate of one-fourth part of the ordinary remuneration added for each mile of the distance between any paupers or parishes and the residence of the district medical officer, the principal de-

\* See "Administration of Medical Relief," pp. 133 and 134. Sherwood and Co., London.

† Ibid. p. 108.

‡ The sums, 2s. 6d. per head, and 6s. 6d. per case, mentioned by the President of the College of Surgeons, if intended as an average, and to include "distance," are decidedly too low (See "Administration of Medical Relief," pp. 70, 107, 108.)

The President seems to prefer a salary calculated on the entire population of the district, varying in ratio merely according to its extent. Were Mr. Guthrie more conversant with the details of the question, he would not have represented the "real objection" to this proposition as "purely theoretical," and "one with which the doctor has no concern." The experience of the last seven years has in truth proved that a salary calculated on the population has no uniform or constant relation to the number of paupers, which differs greatly in different localities. Under Mr. Guthrie's plan, therefore, the amount of medical duty might vary to a considerable extent, without any corresponding variation in medical remuneration—an injustice which may be avoided by adhering to the principle of remuneration sanctioned by the Poor-Law Commissioners.

With respect to midwifery, the President "understands the sum of 20s. to be justly claimed by the surgeon, where the distance from his own house in any ordinary case exceeds two miles." In the absence, however, of any explicit regulation on this head, an attempt should be made to obtain a definite increase of remuneration, proportioned to the distance of each case of midwifery (as of other cases) from the medical officer's residence.

fects in the new regulations could be supplied, and the poor might be properly provided with medical attendance.

To this point, therefore, your committee earnestly request the attention of the Council, believing that a suitable appeal made to the Secretary of State before the passing of the Poor Law Bill might be productive of the most beneficial effects.

It should be observed that the President of the College of Surgeons suggests that the Secretary of State should, if possible, be induced to "empower the Commissioners" to fix the salaries.

This course was recommended by Mr. Serjeant Talfourd\* in 1840; and in case the Government should refuse assent to the enactment of certain limits to medical remuneration in the forthcoming Poor Law Bill, it might be advisable to press for the adoption of Mr. Serjeant Talfourd's and Mr. Guthrie's suggestion, though it appears to your committee even in that case highly important that the principle on which the salaries are to be calculated should be determined by Parliament.

## ADMINISTRATION OF COPAIVA.

COPAIVA is most generally administered by the mouth, but sometimes in the way of clyster. It is often given in too small doses. They ought not to be less than half a drachm; and an entire drachm, given twice or thrice a day, is the most appropriate quantity. As it is a nauseous medicine, on account of the quality, permanence, and adhesiveness of its taste, various devices have been contrived for facilitating its administration. Some take it simply in water, which is stirred briskly so as to collect the copaiva in a globule in the centre. A better plan is to make it into an emulsion. For this purpose each drachm may be triturated with the yolk of one egg, to which are afterwards to be added half an ounce of aromatic, such as peppermint or cinnamon water, and then as much simple water as pleases the patient; or the copaiva may be dissolved in its own volume of spirit of nitrous ether, and then agitated with twice as much mucilage and four times as much water. A favourite method of giving copaiva in recent times is in the form of boluses, made by inclosing the drug in thin capsules of gelatin, which are dissolved in the stomach. This ingenious plan was contrived a few years ago in Paris by M. Mothes, and the process for making the capsules has been kept secret. They may be made in the following manner: the body

\* See "Administration of Medical Relief," p. 131, clause 3.

of the capsule is formed by rounding very smoothly the end of a cylinder of iron or hard wood, four lines in diameter and a few inches in length, dipping half an inch of this end into a saturated alcoholic solution of soap kept warm; then dipping it, when the layer of soap has concentered, into a strong hot solution of gelatin once, or oftener according to the thickness desired; and, lastly, removing the capsule by a screwing motion when the gelatin is quite dry. The top is made in the same way, but shorter and a trifle wider; and when the body is filled and the top slipped over it, they are united by rubbing over the line of junction a camel's-hair brush moistened with hot water (Feder, in Buckner's Repertorium). The form of pill, which, however, is ineligible on account of its insolubility, is best attained by sprinkling one part of calcined magnesia into sixteen parts of copaiva in a flat plate, and letting the compound stand till it thickens sufficiently to be worked into the proper shape. For some time past it has become fashionable in Britain to use what are called specific solutions of copaiva; for which every druggist has his formula, and which have the advantage of presenting the drug in a state of solution, and capable of being diluted without being decomposed. They are commonly made with solution of potash and spirit of nitrous ether, and the following is a convenient formula in use in this city. Boil gently for fifteen minutes two ounces of copaiva with two ounces and a half of aqua potassæ; add, when nearly cool, an ounce of spirit of nitrous ether; and, when the mixture has been at rest for twelve hours, remove the intermediate liquid from the soapy sediment which falls, and the lighter fluid which floats on the surface. In these preparations a part of the volatile oil seems to be separated, and most of the resin deposited in the form of soap. M. Velpeau, not long ago, proposed to administer copaiva in the way of clyster instead of by the mouth. He found it very efficacious when given in divided doses to the extent of an ounce daily in the form of emulsion, to which a little laudanum was added to prevent its too speedy discharge from the gut. Many now prefer the pure volatile oil to any form for administering the crude drug; and though some call in question its superiority, and a few even doubt its efficacy altogether, I am satisfied from observation, as well as many reports from medical friends, that it is at least as effectual as copaiva, efficacious in less doses, and not so apt to occasion sickness. It is best given in emulsion, composed of equal parts of the oil of rectified spirit, peppermint or cinnamon water, and syrup of mucilage. Among the inconveniences attending the use of copaiva, sickness and vomiting are the most frequent. This effect

may sometimes be prevented by multiplying, but diminishing, the doses; by uniting an aromatic water with it, or by directing the patient to chew a piece of cinnamon or nutmeg after each dose. Occasionally a sharp febrile attack is occasioned when the medicine has been taken for some days in gonorrhœa; but as this attack goes off with perspiration in twenty-four or thirty-six hours, and is commonly attended with arrestment of the discharge, it ought not to occasion annoyance, and scarcely requires any treatment. The doses of the preparations of copaivæ are, *Copaivæ*, m. xv. ad fl. scr. iv. *Copaivæ Oleum*, E. m. ad m. xxx.—*Christison's Dispensatory*.

### GALVANIC FORCEPS.

THESE forceps were made by Gorck, the instrument-maker, by order of Dr. Kilian, only to see what might be their effect upon the uterus. The blades are made of copper and zinc, and the metals are properly isolated from the hand of the accoucheur. The first experiment with the galvanic forceps was made upon a woman aged 27, of dry constitution, choleric temperament, and jaundiced complexion. The application of the forceps was decidedly indicated in this case. The head of the child, which was in the first position, remained fixed at the lower aperture of the pelvis; and the torpidity of the uterus was so great, that the child had not moved for two hours and a half; while the infiltration of the scalp was of the size of a man's fist. Before applying the forceps, Dr. Kilian had the patient bled to fourteen ounces; but this had no influence on the action of the uterus. The blades were easily introduced into the uterus; but the moment they were joined, the woman had a fresh pain, which was very violent, without being unbearable. At the same time a movement was felt in the whole uterus, which became as hard as a stone, and lost the morbid sensibility which it had shown before on each examination.

This state of things continued from the beginning to the end of the application of the forceps, and in spite of the hardness of the uterus the pains had no expulsive power. Nothing, however, indicated any spasm of the internal sexual system. After four actions with the forceps, the head cleared the lower aperture of the pelvis, and then (as well as before) the femoral muscles underwent a spasm and trembling of an unprecedented kind. Dr. Kilian then removed his hands from the instrument, to see if the uterus, which was still contracted, would not complete the expulsion of the child's head; but this was not the case, so that he was obliged to continue the use of the forceps.

The infant immediately breathed, which was surprising, when we consider how long it had been fixed in the lower aperture of the pelvis. Hardly were the shoulders free, when the child, which was very strong, began to cry, and the pulsations of the cord immediately ceased. The uterus then contracted, and in five minutes the placenta was in the vagina. There were no pains after delivery, and the lying-in was quite regular.—*Annales de Gand*, and *Gazette des Hôpitaux*.

PORTRAIT OF MR. BRANSBY  
 COOPER.

A VERY striking likeness of this gentleman has been sent to us. The following are the circumstances connected with its execution. The work was undertaken in October 1840, by a Committee of Surgeons' Dressers at Guy's Hospital, six in number. Communications were privately made with various persons, generally medical practitioners, who had pursued their studies under Mr. Cooper; and 200 subscribers, at one guinea each, were soon obtained. The painting was entrusted to Mr. Eddis, of Newman Street, and the engraving to Mr. Simmonds, of Robert Street, Hampstead Road. The former will be placed this year in the Royal Academy. Three hundred copies were struck off prior to the destruction of the plate: of these, 225 have been distributed, and the remaining 75 are now on sale in the hands of the Society for the Relief of Orphans, &c. of Medical Men.

LECTURES  
ON THE  
ANATOMY AND PHYSIOLOGY OF  
THE INTESTINAL CANAL;  
MORE ESPECIALLY OF ITS MUCOUS MEMBRANE.

*Being the Croonian Lectures for 1842,  
delivered at the Coll. of Physicians,*

By R. B. TODD, M.D. F.R.S.

Professor of Physiology in King's College, London,  
and Physician to the King's Coll. Hospital.

LECTURE I.

IN the Gulstonian Lectures which I had the honour to give two years ago in this College, I took for my subject the anatomy and physiology of the stomach. I examined the form of this organ in the various vertebrate classes, and entered at some length into the investigation of that part of it which, in a physiological point of view, is of the greatest importance—namely, its mucous membrane; and I concluded with a brief statement of the principal facts, touching the influence of this membrane upon digestion.

I now propose to call your attention to the anatomy and physiology of the intestinal canal, more especially with reference to its mucous membrane, as being that portion which determines the physiological office of each division of the canal, and which to us, as practical physicians and pathologists, affords the most numerous objects of interest.

And I trust I need not offer any apology for dwelling upon subjects involving so many anatomical considerations, in lectures before the College of Physicians. No medical body has had, among its fellows and members, anatomists and physiologists of higher reputation—men, distinguished as practical physicians, but who nevertheless did not neglect to cultivate those sciences which are universally allowed to be the foundation of their art. The

names of some of the brightest ornaments of our College are as household words, in the lips of the youngest student of anatomy—and must be handed down to the latest posterity, so long as the science continues to be cultivated. And let it not be said, that in these days, when we profit so much by the labours of our predecessors, and when owing in a great degree to the impulse which they gave to anatomical investigations, medicine has advanced to a high state of improvement—let it not be said, that now the College of Physicians is less interested in anatomy than formerly—is less anxious to encourage and promote the pursuit of it among its members.

In former days, the College of Physicians was the “nursing mother” of anatomy, and numbered among its fellows, the sole teachers of that science. The walls of this building afford ample evidence of this fact, in the numerous portraits of those distinguished men, with which they are adorned.

Our greatest boast is of Harvey—respecting whom, Haller says, that his name is, in medicine, second only to that of Hippocrates.

Certain it is, that his discovery of the circulation of the blood was one of the most complete, and its results the most important, that the genius of man ever accomplished. So far as it went, it was perfect; the lapse of more than two centuries has found nothing to add to, or take from, the Harveian doctrine, and having been founded on the certain and immutable basis of anatomy, it must ever continue a leading doctrine of physiology.

Doubtless the singular philosophic caution which Harvey exhibited, in carefully testing the various proofs of his doctrine, during a number of years, before he promulgated it, contributed greatly to its stability. Eight years were spent by this patient observer, in digesting and maturing his ideas; and let me remark, that the example may not be unseasonably quoted at the present day, when there seems to be more ardour in the

pursuit after novelty, than diligence in the investigation of truth.

Harvey was the first who used the simple microscope in anatomical enquiry. He employed it in the dissection of insects, and in observing the growth of the chick in ovo.

Harvey, in a certain degree, anticipated the discovery of auscultation, inasmuch as he availed himself of the assistance of the sense of bearing, to detect the action of the gizzard in birds, as the auscultator uses it, to determine that of the heart. His words are "*Falconibus, aquilis, aliisque avibus ex prædâ viventibus, si aurem prope admoveris, dum ventriculus jejunos est, manifestos intus strepitus, lapillorum illuc ingestorum, invicemque collisorum percipias.*"

We cannot refer to Harvey without likewise alluding to his friend and apologist, the learned Sir George Ent, to whom we are indebted for the publication of Harvey's book "*De Generatione Animalium.*" Ent's dedicatory epistle of this work to the President and Fellows of the College, ought to be read by all who wish fully to appreciate the character of Harvey. Harvey's zeal in the pursuit of truth for its own sake, his singular modesty, his forbearance towards others, and the careful manner in which he conducted his investigations, are brought out in a most interesting manner, in the conversations therein detailed, between him and Ent. One passage I cannot resist quoting, as illustrating the soundness of his views in reference to physiological deduction. "*Natura equidem ipsa, (says Harvey) est arcanorum suorum fidissima interpret: quæ, in uno genere, aut pressius, aut obscurius exhibet; ea clarius et patentius in alio explicuit. Nemo sane de partis alicujus usu, sive officio recte determinaverit; qui ejus, in pluribus animalibus, fabricam, situm, annexa vasa, aliaque accidentia non viderit, secumque diligenter pensitaverit.*"

I need not remark how clearly Harvey has here developed those principles of physiological enquiry, which were subsequently more fully followed out by Haller, Hunter, and Cuvier.

Among the many celebrated anatomists, who flourished in the latter half of the seventeenth century, those, who were Fellows of the College of Physicians, shone pre-eminent. Thomas Wharton lived at this time, after whom the duct of the submaxillary gland was named, and the author of the first complete treatise on the glands—his *Adenographia*—which contains excellent descriptions of the glands, and also of the placenta and ovary. In this work, too, Wharton described the mesentery more fully than had been previously done, and showed, that cellular membrane and other parts were interposed between its layers.

Throughout his book, Wharton makes

frequent mention of another Fellow of our College, whom Boerhaave calls, "*omnium anatomicorum exactissimus*"—namely, Francis Glisson—a name always associated, with the capsule of the liver, which he discovered and described. In addition to his *Anatomia Hepatis*, Glisson published a very learned book "*De Ventriculo et Intestinis,*" in which he has fully described these parts, and added many physiological speculations. He first applied the term irritability, in the sense in which it is now very commonly used, in reference to muscular fibre, and he seems to have had a very clear notion, of what Haller long after described under the name "*vis insita.*" In treating of the *Robur fibrarum*, he says that it is threefold: *Robur, insitum, vitale, et animale*; "*Robur insitum potissimum consistit in fibræ justâ carnositate, et tenacitate:*" and he points out that in emaciated animals, wasted by disease, the muscles are deprived of their usual power—that in the athletic, in whom the muscular flesh is luxuriant, there is extraordinary power—and that in the scorbutic, those labouring under syphilis, and the dropsical, the tenacity of the fibres is impaired, and their power greatly weakened. From all which he infers, "*Fibras, quò carnosiores, et tenaciores fuerint, eò, cæteris paribus, robustiores esse, et fortiores actiones edere, et e contra macilentiores, et friabiliore fuerint, eò debiliores esse, et citius defatigari.*"

A more clear description of the celebrated Hallerian doctrine of the *vis insita*, I apprehend could not be given; and, believing as I do, that certain facts recently ascertained have unequivocally proved the validity of that doctrine, I am the more glad on that account to be able to trace it up to a Fellow of the College of Physicians.

Another of the great anatomists of this age was Thomas Willis—the father, if I may so speak, of the anatomy of the nervous system, upon the functions of which, so much light has been thrown by English physiologists.

Willis's fame rests upon his two principal works; the *Cerebri Anatome, et Nerverum Descriptio*, and *De Animæ Bentorum*.

The name of Willis is associated, with the arterial anastomosis situate at the base of the brain, between the carotids and vertebrals, and with the spinal accessory nerves (*nervus accessorius Willisii*).

Willis first pointed out the anatomical distinctness of the sympathetic nerve from the cerebro-spinal system, although, at the same time, he maintained that a connection existed between them, that the one was engrafted upon the other, *ut frutex super alio frutice*.

No one can peruse the descriptions which this distinguished man has given of the

anatomy of the brain and nerves, without admiring their clearness, and feeling astonished at the knowledge, which he had attained. We are too apt to forget, how much of what we now know, was pointed out by him: the arrangement of the encephalic nerves, which is now in common use, and which, for practical purposes is sufficiently good, we owe to him. His chapter on the actions of the brain and the rete mirabile contains many highly interesting facts, which are being continually quoted, and his views as to the use of the rete mirabile accord with those generally adopted by physiologists, at the present day.

Nor was Willis less distinguished as a chemist, and a practical physician than as an anatomist. For many years he enjoyed a considerable practice in London; and it is well known that he was the first to recognize the saccharine condition of the urine in diabetes.

In the preparation for his work on the brain, Willis derived considerable aid, from the pencil of Sir Christopher Wren. He was assisted likewise, in the anatomical part, by another able Fellow of the College, Dr. Richard Lower, celebrated by his "*Tractatus de Corde*," an anatomist of the highest class, who was also distinguished by the experiment which, in conjunction with Dr. King, and on the suggestion of the celebrated architect Wren, he performed on transfusion. Lower was the first to point out that the difference between arterial and venous blood was occasioned by the action of the atmosphere.

At the latter end of the 17th century lived Grew, better known as a vegetable physiologist, and a botanist, than as an anatomist. It appears that he was elected an honorary fellow of the College, on account of his proficiency in natural knowledge. He was curator of the Royal Society, and printed a catalogue of their museum.

It is not generally known that Grew had discovered, and delineated the glandular patches in the ileum, now so well known by the name of, Peyer's glands. He is certainly equally entitled to be considered the discoverer of these glands, as the anatomist whose name they bear; for in an essay, appended to his catalogue before mentioned, quaintly denominated "*the Comparative Anatomy of the Stomach and Guts*," he had described and figured these patches with great accuracy in several animals, before Peyer's book reached this country. His delineations are more numerous and much more precise, than those of Peyer; and he seems to have been familiar with the characters of the mucous membrane of the intestines, in a great number of animals, and certainly anticipated many points the discovery of

which some of his successors assumed to themselves.

Grew first described the sweat-pores on the fingers, the existence of which many subsequent anatomists doubted, but which modern researches have clearly proved to be the orifices of spiral tubes, the aggregate of which forms the great excretory apparatus of the skin.

Clopton Havers also flourished at this time. The name of this anatomist is connected with the vasculo-medullary canals of bone, now much better known than formerly. This discovery of Havers was not at all appreciated by succeeding anatomists. His description, however, was completely confirmed by Monro primus; and subsequently Mr. Howship, with very imperfect means of observation at his command, described the general arrangement of the larger canals in bone, with more accuracy than any preceding observer. Of late years, Deutsch, Minscher, and others, both in this country and abroad, have, by the aid of modern improved microscopes, determined the true nature of these canals; have shewn them to exist in vast numbers throughout bone, and to be essentially and intimately concerned in its development, as well as in its nutrition: and thus a later age, provided with better instruments of research, has amply asserted the accuracy of this sagacious observer.

I must not omit to refer here to the physician, after whom these lectures have been named. Dr. Croone was an able anatomist, and enjoyed a large share of practice in London. In 1670, he was appointed Lecturer on Anatomy to the Company of Surgeons, and held it to his death. The Croonian Lecture on Muscular Motion, at the Royal Society, was founded by him—a circumstance which alone would associate his name with the theories of muscular action, even had he not written on the subject himself. At the latter end of this period, Edward Tyson lived, whose monographs upon many subjects of comparative anatomy prove him to have been a most accurate and observing person.

His anatomy of a pigmy, of the rattlesnake, of a porpoise, and other papers contained in the *Philosophical Transactions*, are constantly referred to by comparative anatomists, and contain many original observations which have been fully verified in later times. Tyson assisted Samuel Collins, another Fellow of our College, in his well-known *System of Anatomy*.

Although the anatomists of the eighteenth century, who were connected with the College of Physicians, were not less numerous than those of the preceding period, they were not, with few exceptions, so distinguished; nor were their names so connected with original

research as those to whom I have alluded. The names of James Douglas, Wm. Hunter, and Baillie, are among the most distinguished.

James Douglas was the friend, and, in some measure, the preceptor of Haller, during his residence in this country; and that illustrious man always speaks of him in terms of admiration and affection. He is well known by his *Myographia*, and his work on the Peritoneum.

James Douglas was the master of Wm. Hunter, to whose fostering care British anatomy owes so much, and who, were the governments of former days so disposed to favour science as now, would have done much more. Dr. William Hunter's munificent offer made to Lord Bute, the minister of George III., to appropriate £7000, and his museum, to the establishment of an institution for the cultivation of anatomy, was disregarded, and thus his rich collection was lost to this metropolis.

He, however, left behind him a school of anatomists, in Baillie, John Hunter, Cruickshank, and Hewson, who contributed more than others before them, or after them, to raise the character of British anatomy.

The extent to which anatomy has been cultivated in this country, since the time of these distinguished persons, has not been commensurate with our great opportunities, nor does it appear to have been pursued altogether in the spirit of the school of Hunter and of Baillie. The introduction of the French surgical anatomy, or anatomy of regions, although not without considerable utility to the operating surgeon, has, I think, on the whole, been prejudicial to the advancement of that kind of anatomical knowledge, which, as being most conducive to pathology, is best calculated to advance medical science. It has directed attention to investigations of a much easier kind, and thus diverted observers from following out those researches, which bear most directly on the functions of organs. If the physiology of the various textures of the body is to be based on a solid foundation, it can only be done by laying that foundation in an accurate knowledge of their intimate structure; and, if anatomists are to derive practical utility from their labours, they must devote themselves to those investigations, which are most applicable to general pathology.

I trust that the anatomists of the present day begin to feel, that there is something more demanded of them than the mere knowledge of relative position; nay, that they must pry more deeply, into the structure of parts, than they are able to do by the ordinary means at their disposal.

The vast improvement, which has of late years taken place in the construction of the

microscope, leads us to hope much from the use of that instrument, which is now becoming so general. We are scarcely yet in a position to avail ourselves fully of its aid with benefit in the examination of diseased structures; but when, after the lapse of a few years, we shall have acquired a more precise knowledge of the normal structure, it will be incumbent on us to carry our microscopic inquiries fully into the regions of disease.

It is from microscopic anatomy, normal and morbid, aided by the minute analyses of organic chemistry, and accompanied with the careful observation and record of symptoms during life, that pathology is to derive its future advancement. Nor can any one expect to make material improvements in medical knowledge, who is not competent to conduct his inquiries as a minute anatomist, a minute chemist, and a faithful observer and chronicler of morbid actions.

I must apologize, gentlemen, for having digressed so far from the proper subject of this lecture, and shall now proceed to state the arrangement I propose to adopt.

I shall briefly survey the general disposition of the intestinal canal in the vertebrated classes; in the second place I shall consider the rough anatomy of its coats, especially of its mucous membrane; thirdly, I shall make some remarks on mucous membranes in general; and fourthly, I shall describe particularly that of the intestinal canal, making such physiological and pathological deductions as may seem to be warranted by the present state of our knowledge.

The division of the intestinal canal, which all anatomists adopt in the human subject, applies very generally throughout the vertebrate series. We find a small intestine, the main function of which consists in the separation of the nutritious from the excrementitious part of the food, and in the absorption of the latter; and a large intestine, in which a still further elaboration and absorption take place, but whose principal office appears to consist in the elimination of the fecal matter, and its expulsion from the body.

Such being the type of the form of the intestinal canal, we observe much diversity as regards length and width, whether absolutely, or relatively to the length of the body, and several peculiarities in the development of certain parts in relation to, or connection with the intestine, in the various classes, as well as in different orders of the same class.

In Fishes the intestinal canal exhibits a very simple conformation. In many fishes it passes, very nearly in a straight line through the body: when it does exhibit convolutions, they are few and very slightly developed. A pyloric valve is generally present, separating the intestine from the stomach; immediately

succeeding to this valve, the intestine generally experiences a dilatation, whence it gradually contracts to its terminal portion, which again becomes dilated. This portion corresponds to the large intestine, and commonly a valvular fold of the mucous membrane constitutes the internal boundary between the two divisions of the canal; it terminates in a cloaca, common to it with the urinary and genital organs.

Immediately below the pylorus there are found, in most fishes, certain tubular processes communicating with the intestine, but ending in blind extremities, that float in the abdominal cavity. These constitute the *appendices pyloricæ*, or pyloric follicles, which seem to represent that extensive salivary apparatus, which is connected with the first portion of the intestinal canal, in all the higher animals. They vary considerably in number as well as in size. In *ammodytes tobianus* there is only one; in *pleuronectes fesus* (the flounder) there are two very short ones, placed opposite each other at different sides of the intestine; there are from ten to thirty in many species of *clupea* and *salmo*; and in the genera *gadus* and *scomber* (the common mackerel for example) there are as many as two hundred. In some fishes they are simple; in others they become subdivided or branched at their blind extremities; in others these branches undergo considerable subdivision, and the resemblance to the glandular formation is enhanced by the fact, that these branches are connected by means of cellular membrane and blood-vessels.

In reptiles, the intestinal canal differs from that in fishes, chiefly in having undergone a slight increase of development. The division into large and small intestine is distinct throughout the class, and an ileo-cæcal valve is often present. In *ophidia*, the small intestine presents numerous short convolutions at acute angles; the large intestine ends in a cloaca. The intestinal canal is longest in the *chelonis*, and next to them, in the crocodiles.

In the *chelonis*, the line of distinction between large and small intestine is not so obvious as in the rest; the muscular coat is remarkable for its great thickness. In *batrachia* the difference between large and small intestine is very distinct, being chiefly indicated by difference of calibre; and in frogs by a circular ileo-cæcal valve.

In birds the intestinal canal, although longer than in fishes or reptiles, yet retains considerable simplicity of form. It presents much variety in length, and in the number of its convolutions, according to the food and habits of the bird. The most conspicuous portion of the canal is that which is called the duodenum: it succeeds immediately to

the gizzard, and has always the form of a long fold, which contains the pancreas in it, and hangs freely into the abdominal cavity. The small intestine, more or less folded in different orders, terminates in a short and somewhat wider large intestine, which ends in a cloaca, as in fishes and reptiles.

At the commencement of the large intestine in birds, which is much wider than the small intestine, are two processes, terminating in thin and free extremities, and communicating with the cavity of the intestine. These are the *cæca*: they vary considerably as to length, from simple papilliform offsets, as in the Soland goose, to processes three feet in length, as in the grouse. In some instances there is only one cæcum.

Connected with the small intestine there is an appendage, which is the remains of the duct of communication between the yolk bag and the digestive cavity in the chick. In some birds, this appendage, which is devoid of a muscular tunic, is as large or larger than the *cæca*.

In the mammiferous series, great diversity exists in the form and extent of the intestinal canal. Throughout the class, with a very few exceptions, the commencement of the large intestine is marked by a cæcum, which varies much in size and form: the small intestine is convoluted; and the large intestine ends in the rectum, the cavity of which, except in the Monotremata, has no communication with the urinary and genital apparatus.

In the carnivora, insectivora, and the insectivorous genera of bats, we meet instances of the simplest form of the intestine among mammalia. For, not only is it shorter in reference to the length of the body, but its several parts are less fully developed. The small intestine is very slightly convoluted; the cæcum is very short and simple; the large intestine is cylindrical in form, not sacculated, as in man, and many herbivora.

In ruminants, solipeds, and pachydermata, the intestinal canal is characterized by great length, and wide calibre. In the sheep the intestine is thirty times the length of the body. In the horse I have measured the intestine eighty-seven feet and a half; and if we consider the enormous width of the canal, we may form some idea of the immense extent of the intestinal digestive surface. The cæcum is of great size: its capacity in ruminants is about equal to that of their fourth stomach; but in the horse the cæcum is capable of containing more than three times as much liquid as the stomach.

The rodentia have in general a very long, and convoluted intestinal canal. The small intestine is of small calibre, but considerable length. The cæcum is in most of the genera

of very great size, and in some it occupies a large portion of the abdominal cavity. The whole large intestine is cellulated. In omnivorous rodents, as the rat, the cæcum is small; and in one genus, *myoxus* (dormouse), the cæcum is entirely absent; constituting the single exception to the presence of this portion of the canal in the rodent order.

The cetaceous mammalia have an intestinal canal of considerable length. There is, however, a marked difference in length between the intestines of the zoophagous and of the herbivorous whales. In the former division the length of the canal is to that of the body as 11 or 12 to 1; in the latter, as 20, or even 40, to 1. The proper whales have no cæcum: this is the case in the porpoise.

From the brief and very general survey which I have thus taken of the intestinal canal in the vertebrata, it may be gathered that this portion of the digestive tube diminishes in complexity, as we descend from mammalia to fishes; that a short and simple intestinal canal is generally co-existent with a diet of animal food; and, on the other hand, that a diet of vegetable food, or a conjoint animal and vegetable diet, requires greater length, and complexity in the form and structure of the intestines. In estimating the extent of the intestinal canal, we should not confine our examination, as is generally done, to a mere external measurement of length, as we should thereby be led to form a very imperfect estimate. Deficiency in length, as measured on the exterior of the intestine, may be supplied by increased width, by a more highly developed state of the villi of the mucous membrane, by numerous folds of that membrane, and the energy of the action of the mucous membrane on the contents of the intestine may be augmented by the greater number of the glands, which pour their secretions on its surface.

Much importance is attached by physiologists, and apparently with good reason, to the size of the cæcum. It is impossible, in the present state of our knowledge, to determine the law, which influences its development. It may be stated, however, that there appears to be a direct relation between the development of this intestine, and the indigestible nature of the food. In some instances, we find that a very large cæcum compensates for a less capacious stomach, as in the solipeds; and in these cases there exists a striking similarity in the forms of these two organs. Anatomy certainly seems to indicate that the function of the cæcum is not dissimilar to that of the stomach, and that in it substances hard of digestion are subjected a second time to a reducing action, resembling that of the stomach.

## ON THE PULSE.

By the late JAMES HOPE, M.D. F.R.S.\*

Physician to St. George's Hospital.

By the ancients down to Celsus, the pulse was almost overlooked; by Celsus it was pronounced to be *res fallacissima*. Galen subsequently wrote no less than six treatises on it; whence we may, I think, safely infer that to him also, it must have been *res fallacissima*. Nor was the feeling of its ambiguous nature confined to the ancients: for the vast number of elaborate treatises written on the subject, both in this country and abroad, and both before and after the discovery of the circulation, sufficiently evince that a similar feeling has been extensively prevalent among the moderns. So late as the time of Heberden, for instance, the most subtle, over-refined and perplexing distinctions of pulses were universally in vogue. Disgusted and embarrassed by these, Heberden, and his follower Dr. Falconer, cleared the whole away at a single swoop; but, with too rash a hand, they swept away truth indiscriminately with error; for they maintained that *frequency* was "the only circumstance in the pulse of which we can form any clear or determinate idea, and which we can be assured conveys the same information to others as it does to ourselves." Dr. Falconer regarded all "other distinctions as fanciful or whimsical."

I entertain a strong conviction that the main cause of this singular discrepancy of opinion on a subject which has been so long and sedulously investigated, resides in ignorance of the modifications which may be impressed on the pulse by organic diseases of the heart: for I notice in old writers most minute, elaborate, and what might well be thought fanciful descriptions of certain pulses, especially of the intermittent, irregular, and unequal kinds, which I find to be almost, if not altogether, peculiar to certain diseases of the heart wholly unknown to them: if, then, they have misunderstood a single variety of pulse from disease of the heart, we have reason to suspect that

\* Read at the Medico-Chirurgical Society, May 8, 1833.

they may have done the same with respect to others or to all; for of all the diseases of the heart, they were profoundly ignorant.

The modifications imparted to the pulse by this class of diseases, have not, so far as I can discover, been completely and systematically described by any writer down to the present time. The great Corvisart, whose genius penetrated wonderfully deep into a subject which was mystery to his contemporaries, did not possess knowledge enough, without the light of auscultation, successfully to connect the diseased heart and the pulse in the general relations of cause and effect. He succeeded, indeed, in a few instances: but it is manifest, from his occasional inconsistencies, that he felt the sign, in these diseases, to be more than commonly fallacious\*. The illustrious discoverer of auscultation was scarcely more successful. He devotes nearly a whole chapter† to proving that "the exploration of the pulse is far from being able to give an idea of the *general* circulation." "It cannot," says he, "make known the manner in which it is carried on even in the heart‡." He seldom, therefore, mentions the pulse, except as a quotation from Corvisart and others to display its fallaciousness, and to contrast it with the superior advantage of appealing by auscultation to the beat of the heart as a criterion for blood-letting§, &c. MM. Bertin and Bouillaud, in 1824, accurately, though not fully, described the pulses of simple hypertrophy, hypertrophy with dilatation, and hypertrophy with (slight) contraction||; of the pulse of dilatation they merely say that it is "feeble and soft¶;" but as to the pulses of contraction of the valvular orifices, they believe them to be valueless, quote Corvisart to display how totally he was deceived in them, and contend that the auscultatory signs of Laennec are the only indications of valvular disease worthy of confidence\*\*.

How little dependence Dr. Elliotson (in his Lumleyan Lectures in 1830) placed on the pulse, may be collected

from the following observations. "The auscultatory signs are the only means of accurately ascertaining the existence and seat of these affections (viz. hypertrophy, dilatation, and their varieties). The pulse, &c. . . . may all suffer, but the changes induced are too varied for any reliance, any may owe their origin to a thousand other circumstances. In hypertrophy, especially with dilatation, the pulse is frequently full, causing headache, and even apoplexy, if the vessels of the brain are weak or diseased: but when the opening of the mitral or aortic valves is narrowed, it may be very small when the ventricle is hypertrophied, and beats violently. In mere hypertrophy, too, it is small, if the variety is the concentric, i. e. with diminution of cavity. Irregularity of pulse is natural to some persons, so that (in them) regularity occurs only in disease. Irregularity, in others, depends upon disease of the head, stomach, or intestines, or of the lungs. Violence of arterial pulse may be purely functional" (p. 27). "Again," says Dr. Elliotson, "I know that it (a pulse irregular in force and frequency) is very common in the narrowing of the left auriculo-ventricular opening, though possibly not peculiar to it, nor indeed to narrowing of any opening." Of smallness of the pulse in contraction of the left auriculo-ventricular opening, he says, "the importance of this symptom alone is absolutely nothing" (p. 17). In short, like Laennec, Dr. Elliotson depreciates the pulse, and upholds auscultation.

M. Bouillaud, in his treatise in 1835, in consequence, I suppose, of his avowed inability to distinguish the particular valve diseased (an inability which is remarkable, as I had pointed out the mode of effecting this, in my work four years previously), makes a single description of pulse answer for valvular diseases in the aggregate. He says, evidently following Corvisart, "the pulse, irregular, unequal, and intermittent, contrasts by its smallness, its minuteness (*exiguité*), with the energy, the violence, and the extent of the beats of the heart: notwithstanding its smallness, it is hard and vibrating when the contraction is attended with great hypertrophy of the left ventricle\*." I may remark, in passing, that I have

\* e. g. See Bertin, p. 223.

† On the Intermittence of the Beats of the Pulse, vol. ii. p. 473.

‡ Ibid. p. 479.

§ Traité, p. 358.

\*\* Ibid. p. 225.

§ Ibid. p. 480.

¶ Ibid. p. 384.

\* Traité, tom. 2, p. 217.

never seen, and do not believe that there can exist in nature, an irregular, unequal, intermittent, and minutely small pulse, which is simultaneously hard; the qualities being absolutely incompatible. Independent of this, the improbability of a single variety of pulse answering for every variety of valvular disease, is too apparent to require comment, and I shall presently show it to be totally incorrect. In one instance only does M. Bouillaud attempt to connect the pulse with the particular valve contracted, and in this instance he is singularly unfortunate. Still following Corvisart, he says "the pulse is in general more irregular, small, unequal, and intermittent, in simple contraction of the aortic, than of the mitral orifice\*." I have elsewhere shown, and shall presently explain, that the precise converse is the fact†. M. Bouillaud, therefore, has obscured, rather than elucidated, the pulses of the several valvular diseases. He adopts, in his last work, the same pulses for hypertrophy‡ and for dilatation as in the previous treatise of MM. Bertin and Bouillaud, merely adding that hypertrophy with great contraction causes a small weak pulse.

Dr. James Johnson, commenting on the present paper, stated that, after twenty or more years' study of the pulse, in reference both to diseases in general and to those of the heart in particular, he still regarded it as *res fallacissima*.

Thus it appears that, though auscultators have had the merit of attending to the pulses of diseased hearts, they have left the subject in a very imperfect state: to evince how completely it has been pretermitted by non-auscultators—even systematic writers on the pulse—I need only to mention (and it may be done without the slightest disparagement to so distinguished an individual) that Dr. Bostock, one of the most eminent and recent physiological writers, and who may therefore be presumed to represent a large portion of existing opinion, has not made even the most remote allusion to the diseases in question as exercising an influence over the pulse§.

§ See *Cyclopædia of Pract. Med.*—"Pulse," by Dr. Bostock.

I have been endeavouring, since the year 1823, to supply the deficiencies to which I allude; but it is not until lately that the subject has admitted of being brought to anything like a satisfactory conclusion, as discoveries on the pulse could only be consecutive to a succession of other discoveries, which, up to the present time, have gradually been giving additional precision and certainty to the diagnosis of cardiac diseases.

I shall divide the following inquiry into two branches:—

First—I propose to show that the several more important organic diseases of the heart produce corresponding pulses: consequently, that the pulse, usually considered eminently fallacious in these diseases, is really an index of considerable precision.

Secondly—I shall institute a comparison between the pulses of organic disease of the heart and those produced by ordinary causes, to evince that nearly the whole of the latter may be closely imitated by the former: consequently, that an allowance must be made for any coexisting disease of the heart before we can pronounce on the value of the pulse as a sign of ordinary disease: a consideration of great importance in practical medicine.

*I. The several more important diseases of the heart produce corresponding pulses.*

In discussing this branch of the subject, it is necessary for me to explain, as I proceed, the methods which I have adopted, and the discoveries by which I have been assisted, in ascertaining the individual valvular diseases; because many, including so elaborate a writer as M. Bouillaud, question the possibility of ascertaining more than the general fact whether there is, or is not, valvular disease somewhere: and unless I can show the contrary—namely, that it is possible not only to ascertain the general fact, but to specify the particular valve affected, I shall not have an adequate foundation for the doctrine that diseases of particular valves produce corresponding pulses. Further, my data being explained, any one will be competent to verify or disprove what will be advanced, by pursuing a similar line of investigation.

In June 1825, I discovered regurgitation through the mitral valve, and

its characteristic murmur—phenomena previously unknown\*, and which rendered the father of auscultation and his disciples unable to distinguish between mitral and aortic valvular disease. This discovery enabled me to ascertain that the pulse corresponding with mitral regurgitation when considerable, was eminently weak, small, intermittent, irregular, and unequal. The same discovery also enabled me to confirm an observation which I had made two years previously, and recorded in the essays of the Royal Medical Society of Edinburgh in 1824, namely that “it is a peculiar feature of obstruction in the mitral valve that, from imperfect transmission of the blood, and consequently deficient stimulation of the left ventricle, the pulse is small, feeble, and irregular;” identical, in fact, with the pulse of regurgitation†.

I further found, as the exceptions to the general law, that when either the regurgitation or the contraction was not considerable, the pulse might not be materially affected, even though the valve presented the appearance of great disease‡. Though I pointed out these exceptions in my work in 1831, I have observed that they are still so frequently overlooked as to create doubts respecting the general law.

The knowledge of mitral regurgitation and contraction, and of their corresponding pulses, enabled me to correct an error into which Corvisart had fallen, and which was adopted not only by M. Bouillaud as above stated, and by Louis (Mem. on Pericarditis, p. 12), but almost universally; the error, namely, respecting the pulse of contraction of the aortic orifice: “The pulse,” says Corvisart, “may retain a certain degree of hardness and tension, but never much of fulness or regularity.

\* See “Treatise on the Diseases of the Heart,” p. 55. In August 1835, I created mitral regurgitation artificially in the ass poisoned with woorara, in an unpublished experiment, in which I was assisted by Drs. Latham and Watson, and Mr. Mayo.

† Several writers have subsequently noticed this pulse as characteristic of mitral contraction; as Mr. Adams, Dublin Hospital Reports, Vol. iv. p. 420; Dr. Elliotson, who quotes Mr. Adams; Dr. Hodgkin, MEDICAL GAZETTE, Vol. iii. p. 448. Mr. Hodgson had also previously observed that, in this affection, there was often a double pulsation of the heart, i. e. two beats to one at the wrist. One of the two impulses he erroneously ascribes to the contraction of the auricle.

‡ See Cyclopædia of Prac. Med., “Valves of the Heart,” p. 421, by the writer, where the rationale of these pulses is explained.

This invariable and permanent irregularity will always be sufficient to furnish a precise diagnosis of contraction of the aortic orifice\*.” Now this, I submit, is, really, the pulse (though imperfectly described) of mitral contraction and of mitral regurgitation; for, by abstracting the cases of this regurgitation and contraction, which Corvisart had not the means of doing, I found, and have elsewhere proved, by cases†, that the characters of “smallness, and unvariable permanent irregularity,” did not in the least appertain to the pulse of aortic contraction, except when that contraction was extreme—a limited chink only; and that then the characters of *hardness and tension*, obviously incompatible with the other characters, were absent: I found that an induration in the aortic orifice, the size of an ordinary pea, had little effect on the fulness, firmness, and regularity of the pulse; and that slighter degrees of contraction appeared to have no effect on it whatever.

The discovery of mitral regurgitation led me to anticipate, and soon to detect, a similar regurgitation through the semilunar valves, also unknown to Corvisart, Laennec, Bertin and Bouillaud, and all other auscultators. Accordingly, in 1831, I announced that a “murmur may accompany the second sound (of the heart) when there is regurgitation through the aortic valves, and its source may be known by its being louder and more superficial opposite to those valves than elsewhere‡.”

\* Quoted by Bertin and Bouillaud, *Traité*, p. 223.

† Treatise on Diseases of the Heart, p. 332; and cases published in the M&D. GAZ., September 1829.

‡ Treatise on Diseases of the Heart, p. 340. Though the regurgitations and their murmurs were discovered by me, they were first published by Dr. Elliotson in 1830 (Lumleyan Lectures, p. 20). He candidly says, “I heard it” (viz., that a murmur resulted from permanent patency of a cardiac opening) “first from Dr. James Johnson. Who originally suspected it, I cannot say. Dr. Johnson imagined he had learned it from Laennec and other writers upon auscultation; but I have found no other notice of it than the erroneous view of Bertin.” I at first thought that Dr. Johnson learned it from his son, to whom I had communicated it; for, in 1829 and 1830, he and myself studied auscultation together in St. George’s Hospital, and I was in the habit of pointing out the regurgitations to him and the students as a discovery of my own, which Mr. James Johnson says he perfectly recollects; but he thinks that his father was acquainted with regurgitation previous to 1829. However, I was in the habit of demonstrating the regurgitations in St. Bartholomew’s Hospital in 1826, and an instance of this is presented by Case XX. of my

In 1833, 1834, and 1835, when pathologically and experimentally investigating the causes of the second sound of the heart, I acquired a more complete knowledge of the aortic regurgitation, created it artificially in the ass, and found that the corresponding pulse was one of the most remarkable and appreciable produced by disease of the heart; namely, a pre-eminently *jerking pulse*—a high degree of the pulse of unfilled arteries, such as occurs after excessive loss of blood, or in anæmia from any cause. It might, indeed, have been anticipated that aortic regurgitation, by unfilling the arterial system, would produce such a pulse. It has not been noticed, to my knowledge, by any writer up to the present time; but I have taught it for several years in my lectures and clinical demonstrations.

The following discoveries have contributed importantly to facilitate the diagnosis of diseases of the heart, and thus, indirectly, to promote the discovery of the corresponding pulses.

1st, M. Laennec ascribed various murmurs of the heart and arteries, independent of organic disease, to spasm; and considered that, as they could not be distinguished from valvular murmurs, they rendered the latter ambiguous signs of valvular disease. I have shown, by experimental and other evidence, that the murmurs in question are not due to spasm, but to friction and vibration of the blood when deficient and too watery, and that they need not create the slightest ambiguity\*.

2ndly, The series of movements in the heart's action, and their relations to the sounds, mistaken by Laennec, Dr. Corrigan, and others, were finally established by the experiments of the writer in 1830†.

3rdly, In a series of experiments which I invented and performed twice with partial success in October and

November, 1834, and repeated with complete success in the ensuing February (and which have subsequently been repeated by Dublin and London Committees of the British Association), the second sound of the heart was proved, by demonstrative evidence, to result from the closure of the semilunar valves; and the first sound was shewn, by evidence verging upon demonstration, and which I have subsequently corroborated, to be occasioned partly by sudden extension of the auricular valves and chordæ tendineæ, and partly by similar violent extension of the muscular walls at the moment when the valves close; to which "bruit musculaire" contributes a prolongation and possibly an augmentation. Certain commentators on these experiments, who have maintained the first sound to be muscular alone, to the exclusion of valvular sound, have indirectly admitted the valvular sound, and thus subscribed to my view\*.

4thly, Having ascertained that the semilunar valves caused the second sound, I was led to notice a new and very satisfactory method of distinguishing whether disease was seated in the aortic or the pulmonic valves; namely, as the sound, whether healthy or morbid, of each set of valves is propagated up its own artery, the sound of the pulmonic valves may be perfectly heard about two inches up the pulmonary artery on the left, and that of the aortic valves, two inches or more up the aorta on the right, the sound of each set being heard almost independent of the other, which is not the case when the stethoscope is placed directly over the valves. This method has the further immense advantage of removing the auscultator so far from the mitral and tricuspid valves that murmurs seated in them are barely audible, and he can thus assert that a loud, near-sounding murmur, heard two inches up the aorta or pulmonary artery, originates in the semilunar valves or great vessels, and not in the auricular valves.

---

Treatise on the Diseases of the Heart, taken in that hospital June 7th, 1826. In the following year I was in the habit of demonstrating the regurgitations at La Charité, Paris, at the Clinique of M. Chomel.

\* Treatise, p. 64. Since writing the above, I find that Dr. Corrigan had previously made objections to Laennec's spasm, but I have not yet been able to consult his paper. Bouillaud, in 1835, used a train of reasoning similar to my own. The theory of spasm is now universally discarded.

† Treatises on Diseases of the Heart, p. 10.

---

\* For these experiments, see the writer's Treatise on Diseases of the Heart, 2d edit.: Appendix. Dr. Billing, Dr. Carawell, M. Rouanet, Mr. Bryan, and M. Bouillaud, had each inferred the valvular theory of the sounds, but no one had hitherto proved it by direct experiment. M. Bouillaud had even predicted that "the direct or experimental proofs would probably ever be wanting."

Again, I have found that the best situation for exploring the sounds, whether healthy or morbid, of the auricular valves, is not, as has hitherto been supposed, directly over the valves, but where the heart comes in contact with the walls of the chest, so as to present a solid medium for the conduction of the sound. This situation is a little above the apex, and to the left or the right, according as it is wished to explore the mitral or the tricuspid valve. These situations have the further great advantage of being so remote from the semilunar valves, that murmurs originating in them can scarcely be heard: the auscultator may therefore assert that a near-sounding murmur is seated in the mitral valve, or, if he listen more towards the right, in the tricuspid.

5thly, Laennec divided murmurs into the *bellows*, *sawing*, *filig*, and *rasping* varieties, and considered the three latter of these to represent successive gradations of *roughness*; the higher grades being, as he imagined, usually connected with an osseous cause, though this is by no means universally true. The pitch or key of the notes, however, was not noticed by Laennec or any other writer; yet this affords important and easily appreciable information in the diagnosis of the individual valvular diseases. I first directed attention to it in 1831\*, having noticed it in 1825 and 1826 (*e. g.* in Case XX. of my Treatise, dated June 1826); but I have subsequently ascertained the circumstances with more precision.

The key or pitch of murmurs depends mainly on the depth below the surface at which the murmurs are generated, those produced near the surface being on a higher key, and *vice versa*; but the strength of the current producing the murmur has also a slight modifying power, a strong current slightly raising the key, and a weak one depressing it. The following account, founded on much observation, will, I think, be found pretty correct, and, at the same time, easy of comprehension.

Murmurs seated in the pulmonary orifice or artery, from being superficial, are on the highest key like a whisper of the letter *e*, or sometimes of *s*. Murmurs

seated in the ascending aorta, where it approaches near to the sternum, have usually the same character.

Murmurs in the aortic orifice, being rather more deeply seated, are a tone lower, like whispering *r*.\*

Murmurs from aortic and pulmonic regurgitation, on account of the retrograde currents being weaker, are generally a tone lower, like whispering *aw* by inspiration; and the click of the valve, when audible, may be represented by the word *paw*.

Murmurs in the mitral valve, from being still more deeply seated, are still more hollow-toned, like whispering *who*. The tone, however, is somewhat raised by very strong currents, as in violent mitral regurgitation, and depressed by feeble currents, as in diastolic mitral murmurs. Tricuspid murmurs are rather higher toned than mitral, because less deeply seated.

It is scarcely necessary to explain that depth or hollowness of murmurs is referable to remoteness and to reverberation through the chest. For these same reasons, if an *s* or *r* toned murmur, produced in the semilunar valves, be listened to near the apex of the heart, above the clavicles, or on the back, it sounds hollow and remote†.

A murmur on any tone may be either smooth (bellows) or rough (rasping).

Of musical murmurs of the heart, it is merely necessary to say that they indicate nothing more than ordinary murmurs; for in seven or eight cases I have found them follow, accompany, or end in ordinary murmurs. I therefore believe that they are occasioned by an *accidental* configuration of valvular disease calculated to produce musical vibrations, precisely as one configuration of the lips produces a whistle, while another yields merely a blowing sound. M. Bouillaud is of the same opinion, and even employs the same illustration. In all my cases the musical sound has been confined to regurgitations; and I have understood from Mr. Wheatstone that the presentation of an edge to a stream is the arrangement best calculated to produce musical vibrations. It remains, therefore, to be seen whether musical tones afford pre-

\* For the ingenious idea of these two letters, *s* and *r*, I am indebted to M. Bouillaud, though he employs them somewhat differently.

† I find that Dr. Elliotson has noticed this effect of distance, in his Lumleyan lectures.

sumptions of regurgitation rather than of direct valvular obstructions.

Attention to the rules now given, respecting the situations in which vascular diseases ought to be explored, and respecting the various keys which murmurs present according to their seats, renders it as easy to pronounce which is the particular valve diseased as to say whether there be valvular disease at all. Further, an auscultator capable of making this particular diagnosis is far less liable than others to be misled by inorganic murmurs of the heart; since, if the murmur proceed from a regurgitation, or be seated in any other orifice than the aortic, he can decide at once that it is organic.

Assuming it, then, to be true that particular valvular diagnosis is possible, we have data by which we can ascertain the pulses corresponding with valvular affections—the establishment of which fact was indispensable to the prosecution of the present inquiry.

Such are the several grounds on which I found the opinion that the more important diseases of the heart are productive of corresponding pulses. We next proceed to the second branch of the subject.

[To be continued.]

---

CASES OF  
SUBCONJUNCTIVAL DISLOCATION  
OF THE LENS,  
AND OF SUBCONJUNCTIVAL TUMOR OF THE  
VITREOUS HUMOUR.

---

*To the Editor of the Medical Gazette.*

SIR,

IN the MED. GAZETTE, vol. xiii. p. 833, amongst my "Observations on a Peculiar Dislocation of the Lens," will be found some strictures on the conduct of Mr. Lawrence\*, in consequence of that gentleman having incorrectly quoted the report of a case of this description published in the MED. GAZETTE†. On referring to Mr. Lawrence's second edition, recently published, I am glad to find that he has withdrawn the objectionable passage‡. Mr. Lawrence has also, in the same page, referred

to the following case reported by Dr. Mackenzie, and illustrated by an explanatory delineation of the eye. "The annexed figure represents the effects of two different accidents, which, at the interval of some years, befel the right eye of an old man, the first patient in whom I happened to meet with a subconjunctival dislocation of the lens. On inquiring into the history of his case, he told me that the separation of the iris, represented in the figure, had been the result of the earlier accident, but that the tumor which I saw at the upper part of his eye was the consequence of a recent fall on the corner of a chair. The tumor had exactly the form of the lens, and the natural pupil was dragged towards it. On laying open the conjunctiva, the crystalline was easily withdrawn. The opening through the choroid and sclerotica, by which it had escaped, seemed already perfectly united. The retina was no wise impaired, notwithstanding the serious effects produced on the other textures of the eye by the two accidents, and with a cataract glass the patient could read an ordinary type\*."

In its result this case was still more favourable than that of Syddal†, which may probably be attributed to the following circumstances:—The former injury, in consequence of which the iris was detached from the ciliary ligament, would leave the portion of iris thus detached in a relaxed state, so as to allow of the internal structures of the eye more readily yielding to the pressure, caused by the second accident, which produced the dislocation of the lens; and, by this means, prevent them from suffering so much afterwards. The opening in the choroid and sclerotic coats "seemed already perfectly united" in Dr. Mackenzie's case, whilst in mine there was a subsequent tumor, caused by protrusion of the vitreous humour, and the laceration remains ununited. In both instances the lens was removed at an early period after the occurrence of the injury which had produced its dislocation—a plan of treatment which appears calculated to prevent the destructive changes consequent upon such injuries, which generally terminate in the loss of vision. Such, at least,

---

† MED. GAZETTE, vol. ix. p. 178; and vol. xiii. p. 832.

was the consequence in the instances to which reference is made in my former communication\*, and also in the following.

**CASE.**—William Weavers, æt. 64, received a violent blow on the left eye, from a man's fist, more than five weeks since, which caused at the time severe pain and swelling, and loss of vision.

March 8th, 1841.—The upper part of the cornea had now become opaque, sloughy, and ulcerated; but the centre remained sufficiently transparent to allow of the examination of the pupil, which was contracted, fixed, and nearly filled with pus. At the upper part of the globe, a short distance behind the corneal and sclerotic junction, there was a circumscribed semi-transparent tumor of the conjunctiva, which both Mr. Barton and myself considered to be caused by the dislocated lens. I therefore divided the conjunctiva with a cornea knife, and extracted the lens inclosed in the unruptured capsule, both structures being perfectly transparent. I also punctured the lower part of the cornea, to relieve the eyeball from the distension occasioned by internal suppuration. He suffered much less after the removal of the lens, all the inflammatory symptoms subsided, and the eye gradually sank into a state of atrophy.

*Case of a tumor of the conjunctiva, caused by injury, closely resembling that produced by subconjunctival dislocation of the lens.*

March 26th, 1841.—James Howarth, a carter, æt. 38: fifteen days since was struck on the left eye by a piece of dirt, which had been thrown at him. The cornea was perfectly transparent, the pupil much dilated and irregular, making the iris almost of a horse-shoe shape. The pupil was clear, and the lens apparently absent. There was a distinctly circumscribed tumor of the conjunctiva on the superior part of the globe, presenting external characters similar to those found in the sub-conjunctival dislocation of the lens. The conjunctiva covering the tumor and upper part of the sclerotica was very vascular, the other portion not much more so than usual. Vision was much impaired, but not entirely lost. Upon puncturing the tumor with a cornea-

knife, no lens was found, the swelling having been entirely dependent upon an extensive protrusion of vitreous humour through a laceration of the sclerotica. The eye was kept closed by means of strips of court-plaster for two days, after which the nitrate of silver was repeatedly applied to the tumor, which, although reduced by having been punctured, remained for some time so prominent as to cause pain on motion of the eyelid. The other part of the treatment consisted in the free use of the saturnine lotion, a blister to the temple, and common aperients. When I saw the case two months afterwards, there was, in the situation of the injury, a slight fulness of the conjunctiva, which was so thickened as to prevent my ascertaining if the sclerotica had healed; the pupil was still dilated, irregular, and immoveable, and no useful vision remained. This case shows that it may sometimes be difficult to form a correct diagnosis of the nature of such tumors of the conjunctiva. But if the swelling be caused, not by the displaced lens, but by protruded vitreous humour, the practice of dividing the conjunctiva should, nevertheless, be adopted; for although effects equally destructive with those which supervene upon subconjunctival dislocation of the lens do not follow the injury, yet the process of reparation appears to be facilitated by puncturing the conjunctiva, and thus giving a free exit to the portion of vitreous humour lying extravasated between it and the sclerotica. The entire removal of the tumor is not, indeed, thus effected; fresh portions of vitreous humour continuing to protrude through the sclerotica as long as the laceration remains open: but, by the repeated application of the nitrate of silver, such an adhesion of the subconjunctival cellular texture situated over the laceration is procured, as eventually precludes any further protrusion of vitreous humour. What is called sclerotic staphyloma is frequently caused by similar injuries. In one instance, which came under my notice many years after the accident had occurred, the appearance of the tumor, cornea, and pupil, closely resembled that recorded in Howarth's case; with the exception that the tumor presented the dark bluish colour usual in cases of sclerotic staphyloma.

\* *MÉDICAL GAZETTE*, vol. xiii. p. 332.

All irritation from the effects of the injury had, according to the patient's account, long since subsided, and his imperfect vision was much improved by the use of a cataract glass, which, in consequence of the dilatation of the pupil, was inclosed in a broad black rim.

Notices of other cases of subconjunctival tumors produced by dislocation of the lens, and by protrusion of the vitreous humour, will be found recorded, by Mr. Middlemore, in the Report of the Birmingham Eye Infirmary, published in the ninth volume of the Transactions of the Provincial Medical and Surgical Association, pages 508-510.—I am, sir,

Your obedient servant,

R. T. HUNT.

Manchester, May 12, 1842.

#### OBSERVATIONS

##### ON THE

#### TREATMENT OF FRACTURE OF THE NECK OF THE THIGH-BONE.

BY A MEDICAL OFFICER OF THE ARMY.

(For the Medical Gazette.)

I BELIEVE it will be generally admitted that no subject of surgical treatment has been more unsuccessful in its results than in cases of fracture of the neck of the femur; and it has appeared to me, that the explanations or apologies for our failures in such cases has been anything but satisfactory, or even in accordance with what is known and regularly inculcated, of the effect of pressure on the most solid parts of the animal frame. At present I merely allude to those cases of failure which have been imputed to the circumstance of the fracture having been within the capsular ligament, and that there, that membrane intervening between the fractured portion of the bone, prevents the ossification of the fractured parts. I shall not notice what is generally known and assented to, that pressure against such an intermediate substance would most certainly, in a person of a sound constitution, occasion in time the absorption of the intervening obstacle to the re-union of the bone; but I will venture to affirm, that even cases of fracture of the neck of the femur within the capsular ligament,

although the person injured would become immediately lame, still the distortion of the limb, at the seat of the injury, would not be easily ascertained even by the most practised and discerning examination, unless the fracture had been occasioned by extraordinary external violence.

In cases of the description which I now speak of, practitioners seem to me to have lost sight, and never considered the import and utility, of the ligamentum rotundum which binds the head of the femur to the acetabulum. Without this wonderful piece of mechanism, a person moving in the horizontal position, or even in walking upon an uneven surface, would be in continual danger of dislocating the femur. In this view of the matter, I therefore maintain that, as the humble servants of nature, we should endeavour to follow her dictates in presuming to rectify any irregularity that happens in the wise and beneficent purposes of Providence. It is probably, in a great measure, owing to the rupture of the round ligament in cases of dislocation of the thigh, that a certain lameness always inconveniences the sufferer after it has been reduced, attended with a considerable swelling or fulness of the muscles adjoining the trochanter, particularly on every attempt to move the limb. If the opinion thus surmised be correct, it will be easily understood that, on a fracture of the neck of the femur taking place, the body of the bone being thereby disconnected with the acetabulum, it will, by its weight, naturally recede from the broken portion within the acetabulum, even by the best contrived bandaging for securing the apposition of the fractured parts, unless some means are had recourse to in order to support and maintain the trochanter in its healthy position: it is from neglect to this part of the treatment, as commonly practised, that I am inclined to suppose that in a great degree our failure in obtaining a cure in such cases of fracture is to be imputed; for I think that in a just apposition of the fractured ends of the bone no intervening substance could possibly prevent an ultimate re-union of the parts. I shall now, in a summary way, state a case or two in proof of the propriety of the practice I have hinted at: the parties being my friends, although not under my care, every cir-

cumstance of their cases was very well known to me.

The first is the wife of a physician, a lady past the meridian of life, weakly, of a spare habit: had her right thigh-bone broken at the neck by something taking her foot as she walked through the drawing-room: when laid upon the sofa, her husband could not perceive any particular injury where she complained of pain; and in this state she was carried to bed: she passed the night in much pain in the part; and it was not till from twenty to thirty hours elapsed that the nature of the accident was ascertained. The fracture was reduced when she had been laid on a firm mattress; a firm bandage was tightly bound round the pelvis, and the limb being stretched in a straight line was bound in such a manner as to prevent all motion in it. She luckily escaped any feverish symptom; but in the course of a few weeks her husband got a cushion made to slip under the back, in order to relieve the intolerable pain and uneasiness she experienced from laying so long in the recumbent posture upon an unyielding surface: this cushion also gave support to the trochanter, and happily, at the end of four months, on the bandages being taken off, a perfect re-union of the bone was found to have taken place. This lady is now perfectly well, and the lameness but very little to be noticed.

The next case I shall mention is the wife of a colonel in our army. She is about the same age as the above, of a full habit, subject to inflammatory affections of the chest, and has suffered from gout: the neck of the thigh-bone was fractured, by her being blown over in a high wind when walking on an uneven surface. Her accident happened a month or two previously to that of the case above mentioned: they were attended by the same practitioner, and the same mode of treatment adopted—the bandaging of the outstretched limb, &c. &c. This lady had occasion to be bled and leeches during the first months of her confinement; but unluckily, on the bandages being removed at the end of four months, it was found that the bone had not only not united, but that the fracture was in every way as upon the occurrence of the accident. Upon this occasion her husband was earnestly recommended to have a similar cushion used

as in the former case, upon the fracture being reduced; and to the satisfaction of all her friends it was found, on removing the bandages, after laying four months more in the recumbent posture, that the bone was perfectly united: perhaps an unique case in the annals of surgery, that a bone should unite after several months' separation. I have seen this lady repeatedly since her cure: the motion of the hip-joint is perfect; but although the knee-joint is not affected, in consequence of the straight position in which the limb was placed, and the bandaging, the muscles have thereby lost their natural action; and from this cause she cannot bend her leg. The heel is also drawn up, owing, as I suppose, to so long confinement in one posture, and the consequent contraction, and perhaps the conglutination, of the fibres of the flexor muscles. In other respects she enjoys her usual health.

I shall next mention the case of a lady about forty years of age, the wife of a surgeon to an hospital. The accident occurred when playing at shuttlecock with her children in the drawing-room. In this case, also, the nature of the injury was not immediately discovered. When I saw her, a few days after, she was lying in a soft bed, with a bandage round the pelvis; the limb laid straight, but not bandaged.

In this case, I have no doubt, the trochanter was supported and maintained in its natural position by the pressure of the mattresses of the bed, which were not firm, as in the former cases, but soft and yielding: this lady very soon recovered the use of her limb, without any remarkable lameness. I could, to the above, add other cases, where, I believe, a fracture of the neck of the thigh-bone had taken place within the capsular ligament, and the protuberance of the fractured bone not being discernible on the first examination, the disease has been treated as a severe bruise, and which terminated in permanent misery and lameness; or if the true nature of the injury has at length been discovered, the failure of the cure has been imputed to the intervention of the capsular ligament between the ends of the broken bone. The inference I draw from the foregoing statement is, in the first place, that every means should be adopted for securing

the apposition of the fractured ends of the bone, and that this view is mainly to be effected by supporting the great body of the femur, which otherwise, from its weight, must recede from and sink under the surface of the broken portion, remaining fixed in the acetabulum: an inspection of the skeleton must satisfy the most superficial that such will be the consequence when the person, having the neck of the femur broken, is laid upon his back. I do not see the necessity of placing the patient, in this state, upon a hard, unyielding mattress. I know it often occasions intolerable distress to the patient, and may therefore protract, if not interrupt, the cure: a mattress in ordinary use will obviate many of these inconveniences. The fracture being reduced, the limb should be laid in a bent position, as in other fractures of the femur, so that all the muscles may be in a state of complete relaxation; and after the bandage is firmly secured round the pelvis, a long cushion of horse-hair, about six or eight inches in breadth, according to the bulk of the patient, and about the same thickness, and so long as to reach from the under and upper part of the os ilium, and going under the trochanter to a few inches below it. This cushion should be secured with tapes at each end to fix round the body and the thigh, and should be carefully examined every day to see that it does not shift its place: or to avoid the chance of this happening, the bandage around the pelvis might be so constructed as to give the necessary support to the thigh. In this way the cure of such cases will be more certain, and require less time than the practice now in general use.

#### CIRCULATION IN THE BRAIN.

*To the Editor of the Medical Gazette.*

SIR,

IN your last number Dr. Haworth, of Bolton, still argues that the cerebral circulation "feels the full force of atmospheric pressure," and that the experiments of Dr. Kellie are not opposed to his views. It will not require much consideration to show that not only these experiments, but even the statements of Dr. H. himself, clearly prove that there is no pressure whatever exercised by the power in question on the circula-

tion in the brain. If I understand Dr. H., which I confess is not a very easy matter, he affirms that the cerebral circulation is influenced by atmospheric pressure through means of the blood-vessels which enter the cranium from without; this pressure, in the first instance, being exercised on these "vessels before they reach the brain," "and that they feel the full force of it after;" that the pressure is *conveyed* to the minutest ramifications of these vessels; and thus we have the atmospheric pressure exercised upon the whole contents of the cranium, from the centre to the mass. These views, I hold, are both highly erroneous and self-contradictory.

1. In order to prove his opinion, Dr. H. compares "the skull, its contents and connected vessels, to a long-necked globular bottle filled with water, &c. and turned upside down, the narrow part corresponding to the blood-vessels, and the globular part to the skull and brain"!! Surely Dr. H. does not seriously intend to pass this off for an argument? He cannot be so entirely ignorant of the rules of reasoning as to bring forward illustrations in proof of his assertions. What analogy can possibly exist between the circulation of the blood in the brain, and a globular bottle filled with water and turned upside down? If the blood-vessels and nerves entered the brain at a certain point only, and if their external surface were subjected to atmospheric pressure in the same manner as the water in the bottle, then Dr. Haworth might have some slight shade of plausibility for tracing an analogy between them; if this even existed, and if the "atmospheric pressure could be no more denied in the one case than in the other," instead of Dr. Haworth's views receiving any confirmation from the circumstance, they would stand confuted, because this would prove too much for him, inasmuch as not a single drop of blood could make its escape from the cavity of the cranium, until the atmospheric pressure was admitted in an opposite direction. The same remarks will equally apply to his illustration "of the egg broken at one end," which he pronounces as analogous to the circulation in the brain.

2. Dr. H. seems to have overlooked the fact, that blood-vessels emerge from

the brain through the skull, as well as enter it from without. Now if it be true that atmospheric pressure is exercised upon the latter class of vessels, and if it be true that these vessels convey this pressure to their minutest ramifications, it must necessarily be carried to those vessels which emerge from the skull, as, according to Dr. H., confined fluids transmit pressure to any amount to any distance:" besides this, the vessels which come out from the brain must be submitted to the same atmospheric pressure at the moment they reach the surface, and in the same manner, as those which enter through the skull convey this pressure to parts within the cranium. Now, according to this, the cerebral circulation must be completely under the influence of atmospheric pressure—a pressure exercised not only from the centre to the circumference, but from the circumference to the centre. Here again the views of Dr. H. stand confuted upon his own shewing. If such pressure as he contends for were exercised, as we have already seen, it would prevent any escape of blood from the brain; and by extending his principles to the vessels which emerge from the skull, we see that blood-letting would completely empty that cavity—a circumstance which he admits to be impossible in ordinary circumstances.

3. Admitting that the atmospheric pressure is exercised upon the blood-vessels without the cranium, it does not follow that this pressure is communicated to the blood-vessels within the skull, as Dr. H. asserts it to be; I think the foregoing observations disprove the assertion. We have seen that the idea of a pressure from the centre to the circumference is absurd, and that pressure of the atmosphere, in the ordinary acceptation of the term, is impossible. But we have not only reasoning to advance against the absurdity of atmospheric pressure being conveyed to the brain through the means of the blood-vessels and nerves, but we have actual observations and experiments to prove that no such communicability of pressure takes place. Dr. Kellie and others have observed that, in the brains of executed criminals, there was not the slightest trace of congestion of the blood-vessels, whilst those on the outside of the skull were most immoderately distended, and

even ruptured. Dr. K. strangled dogs, and neither congestion nor extravasation was found within the head, whilst both existed to the greatest degree without. Now if the principle of "confined fluids transmitting pressure to any amount to any extent" be applicable to the circulation of the blood in the brain, and if the atmosphere act on the brain as Dr. H. imagines, we would expect to have found matters in a very different condition. It were useless to protract this discussion any farther. It is, I think, sufficiently proved that the views of Dr. H. are completely at variance with the experiments of Dr. Kellie—the original assertion which I made.

I would beg to inform Dr. H. that I am not singular in my opinion respecting these experiments proving the exemption of the cerebral circulation from atmospheric pressure. Dr. Kellie himself took the same view, and assigns this as the very reason why blood-letting does not empty the blood-vessels of the brain.

Besides several others who have publicly expressed the same opinion, Dr. Watson of London, in his admirable lectures, now in the course of publication in the *MEDICAL GAZETTE*, takes the very same view, and makes allusion to these very experiments, as proving the circumstance, and at the same time he states, that he has confirmed several of Dr. K.'s observations by his own personal experience. I would refer Dr. H. to page 471 of your 28th vol. for satisfaction on this point. In conclusion, I would observe, that so far as I am concerned, this discussion is at an end. Any of your readers who may feel interested in the subject, by a perusal of the experiments to which allusion has been so often made can easily determine whether Dr. H. or your humble correspondent have taken the legitimate view of their bearing upon the point at issue between us. If in my "own anxiety to stop the progress of erroneous opinions," I may have caused any unpleasant feelings to arise in the mind either of their originator or his friends, I sincerely regret it.—I am, sir,

Your obedient servant,  
JOSEPH BELL.

Barrhead, May 11, 1842.

## MESMERISM.

*To the Editor of the Medical Gazette.*

SIR,

I SHALL inclose with this letter a slip of paper, informing you of my name and address, and you will recognise in me an old contributor to your columns. I do not choose to put my name to this communication, for this good reason among others, that I wish to escape being assailed with a multiplicity of questionings by my numerous acquaintance here. About one o'clock the day before yesterday I was sent for in a great hurry, to see the butler of a lady in the neighbourhood, who had just fallen from a ladder. I found he had received a heavy blow on the head, accompanied with a slight lacerated wound of the scalp, a severe bruise on the left arm, with some abrasion of the cuticle, and an extensive bruise over the sacrum and left hip. He was cold, pallid, with small pulse, and complained of feeling very sick. He seemed to be suffering severe pain in the injured parts, and (as is usual among the Irish in his station of life) was sufficiently energetic in the expression of his suffering. As the system had evidently received a shock, I ordered warm fomentations to the injured parts, prescribed a stimulant, and said I would see him again in an hour or two. On making my report to the lady, she said, "You'll think me very ridiculous, but I have one thing to ask of you." "What is it?" "Have you any objections to my mesmerising him?" "Not the least in the world." "How long may I keep him asleep?" "As long as you like; until to-morrow morning if you can." "But won't there be some danger?" "I don't think there is much danger of the sleep *you* are likely to give him." "Well, I see you are determined not to believe in mesmerism; but I shall try it on him if I have your permission." "You may mesmerise him as much as you please," was my reply. On calling about two hours after, I found him warm, with his pulse and colour restored, and in a tranquil sleep. I learned from the gardener, who was officiating as his nurse, that after he had assiduously fomented him for some time, during which he had com-

plained bitterly of his sufferings, the lady had come in, and sent him to sleep by mesmerism. I did not much heed the mesmeric part of the story, but thinking him going on well, I left directions to be sent for if he got worse. I had a note from the lady late that evening, saying that he woke up at five o'clock in a good deal of pain, but that on having recourse to mesmerism he had fallen asleep again, and so continued.

I called yesterday, and before seeing him I had a long introductory narrative from his mistress of the wonderful benignant effects her manipulations had produced on him. I do not recollect particulars, for I paid but slight attention to the relation, being pressed for time, and my thoughts wandering about some appointments I feared I should not be able to keep. On seeing the man I found him going on very well, with very little headache, and complaining only of the soreness of his bruises. I hastily asked him a few questions. He affirmed that the mesmeric passes always took away his pains; but I recollect there was this discrepancy between his statement and that of his mistress,—she said it took only five minutes to relieve his pain and send him to sleep, whereas he said it took a quarter of an hour. I prescribed an active aperient, and left him.

On going this morning, the servant was about to show me into a sitting-room, but I chose to go straight to the man's bed-room. On entering I found him fast asleep. I spoke to him, called him, shook him, pinched him, but could not wake him. Leaving his room, I met the lady, who said, "You won't be able to wake him, he is in a mesmeric sleep; I will go and wake him for you." She went back with me into the room. He was lying in bed on his right side, with his face to the wall, but inclined upwards; so that we stood at his back. She was about to wake him up, when I said, "Stop! I think I have heard they cannot feel in this state; let me try." I took out my pocket case, and as his left arm was lying out of bed, I smartly pinched the back of his hand several times with a sharp pointed forceps, but he gave no indication of feeling. I then attacked his whiskers with the same instrument, and pulled out several hairs one after

another; but still no indication of feeling. "Won't you believe now?" says the lady: "are you not convinced now?" "I confess I am rather astonished," I replied. "I'll try if I can put this arm into a cataleptic state," said the lady. She raised it up until it was perpendicular to his body, and while busy in making the passes, with her head directed away from me, I took out my tenaculum, and softly carrying it through the bed-clothes, having a fair mark, and measuring my distance well, I gave him at least a quarter of an inch of its point in his gluteal region, and repeated the thrust. I fully expected a start and a yell that would have electrified the magnetiser; but not a muscle moved, not a feature changed. This by-play of mine passed while the lady thought I was intent on her manipulations, and to the present moment she knows nothing of it. She succeeded in fixing his arm, and it required great force to remove it from the position she had placed it in. After waking him she left me alone with him. I had known the man for years, have attended him professionally on three or four occasions, and should never have suspected him of trying to deceive, or playing tricks. However, I charged him with it rather roughly, and said he ought to be ashamed of trying to make a fool of me in that way. He declared his innocence with every appearance of sincerity, and I, after upbraiding him and cross-questioning him for some time, left him, with, if possible, the increased conviction, that he had been completely insensible to my rough treatment, and was not aware of my presence until he was awakened by his mistress. During his apparent sleep he readily answered the questions of his mistress; said he felt cold and sick, and that he would wake up if he could. He also imperfectly answered questions I put to him, after I had loudly repeated them to him, which the lady said he ought not to have done, according to the usually observed effects of the mesmeric art. I am at a loss to know how any man (and that man particularly) could sham so well, as not to evince pain upon having a tenaculum thrust into his posteriors.

I fear the length of this communication will have exceeded the space you can well afford it, and I must therefore

abstain from further remarks, but I will subscribe myself, what I have always been inclined to be,

A MINIMIFIDIAN.

### THE DEBATE ON MILITARY FLOGGING.

EVERY one must have remarked that when the tide is rising on the sea-shore, its progress is often dubious to the careless observer. Although certain to push forward its waves to the beach which they are ultimately to cover, advance alternates with retreat; and sometimes an advance is so distinctly less than the previous one, that it is really a kind of retreat, so that the spectator has good excuse for his mistake.

Just so it is with truth; its advances are often slow, and sometimes, alas! exchanged for retreats; so that the hypochondriacal have occasion to fear that the good cause is lost, and that instead of increase of light, we are likely to be overwhelmed with primæval darkness. But truth is immortal, and can bide her time; the tide rises, and will ultimately level the cliffs which it seems yet unable to attain.

Again, while the great body of water goes on, individual drops may be hurried back by the wind into the ocean which they have left, and thus be rendered incapable of covering the coast which, just now, they seemed certain to reach.

The advancing and retreating tide is but an image of human opinions; and while some go on manfully till

they have levelled the abuse which first excited their indignation, others hurry back into the ocean of doubt, and shrink from the realization of their own wishes.

Captain Boldero is in this predicament: he was once the declared opponent of military flogging, the most flagrant violation of humanity still practised in these islands; he is now its declared advocate.

Whether, with the present composition of the British army, it might be possible instantly to abolish military flogging, we will not pretend to say; but we freely confess that the predictions to the contrary, the assurances that its abolition would be equivalent to disbanding the army, though uttered by men of note, have but little influence upon us. Vaticinations equally lugubrious, and always falsified by the event, will occur to every one's memory. Who does not recollect that glib argument for the capital punishment of forgery—that England, being a commercial country, could subsist only by credit; and credit only by the extermination of forgery? Yet with unchange'd forgers, credit and commerce remain. So it might be found in the present case. But granting that the punishment must be continued for the present, it might assuredly be further limited, both in the number of offences to which it is applicable, and in the number of lashes inflicted.

How stands the question at present? On the 15th of last month, Captain Bernal, in the House of Commons, proposed the abolition of military flogging, in time of peace, excepting in cases of theft, or on line of march; and he prefaced his motion by some calm and judicious observations, including a short history of the mitigation of the practice. Before 1812, even a regimental court-martial was unlimited in the number of lashes which it might inflict. In

that year the maximum was fixed at 300. In 1830, the greatest number to be inflicted by a district court-martial was *limited* to 500. Finally, in 1836, the punishment was limited, by sentence of a general court-martial, to 200 lashes; by sentence of a district court-martial, to 150; by sentence of a regimental court-martial, to 100.

Nor must we forget to mention that, in 1833, the offences to which the punishment is applicable, were defined, with one exception. This single exception occurs in the phrase "other disgraceful conduct," which might easily be made to include a variety of peccadilloes not worthy of so terrible a penalty. This limitation took place in consequence of a strong minority in the lower house, on a motion for the abolition of corporal punishment; the numbers having been 140 to 151. So excellent is discussion, and so sure to produce good fruit!

Two apposite instances were alleged by Captain Bernal to show the possibility of maintaining discipline without flogging.

One was the abolition of flogging among the native troops in India by Lord William Bentinck. "There is an unanimous agreement in all the committees," said his Lordship, "that flogging, however degrading and injurious, cannot entirely be abolished. They do not even stop for a moment to inquire into the practicability of an adequate substitute. With them corporal punishment is the *sine qua non*, without which the discipline of the army cannot be maintained. I denounce this opinion as prejudice, because it is opposed to reason. Though I am not surprised at the opinion, I cannot forget that, for many years, in conjunction with ninety-nine hundred parts of the officers of the British army, I entertained the same sentiments. It is only from my reflection and discus-

sion that my own prejudice has given way. I now feel confident that this degradation will speedily disappear before a more reasonable and enlightened legislation, even in the British army."

The other example, usefully, but less completely apposite, is that of the Irish constabulary force. It consists of 7000 picked men, who are drilled among the regular troops, but not flogged with them.

But it may be answered, and has been answered, that the constabulary force is better paid than the regular troops. True; it is one of the disadvantages in our army that the pay is too low to be a permanent attraction. Hence, a young man of the lower classes rarely enters the army with the consent of his parents, as Adam Smith long ago observed; and hence arise the various frauds which are practised to escape from the service\*. When, to the slenderness of their pay, and the restraint under which they live, we add the boyish age at which many of them are decoyed into the service, can we wonder that the terrors of the lash should be required to keep them at their work? In other employments, instant and unconditional dismissal is a threat held out to the incorrigible; here it would too often be welcomed like a fountain in the desert. "The greater part of the recruits," said Capt. Bernal, in his speech, "were boys of sixteen, entrapped under the excitement of liquor, and deceived by the false promises of pay and promotion held out by the recruiting sergeant."

Enlistment for a term of years, which Capt. Bernal advocates together with Windham, Wilberforce, Lord Lynedoch,

---

\* "Soldiers commonly maim themselves to obtain their discharge, and sometimes even to become convicts, as was the case in New South Wales a few years ago. The men were ordered to be kept in the regiment to which they belonged, and to perform the duties of scavengers."—*Marshall on the Enlisting, &c. of Soldiers*, 2d edit. p. 145.

and Major General Archibald Campbell, would undoubtedly sweeten many of the hardships of the service. It would be the best preventive of that despair which too often seizes upon the soldier who has enlisted for life. Of the deaths which take place in the cavalry, says Mr. Marshall, one in twenty is the result of suicide.

Captain Boldero denies having voted in favour of the abolition of corporal punishment more than once; namely, in 1836. In 1838, (such is his present interpretation,) he only asked for a select committee to inquire into the state of military punishments and rewards in the British army. Some honourable members have undoubtedly attained that art which Themistocles was desirous to learn—the art of forgetfulness; and though Capt. Boldero, in 1838, may not have moved in direct terms for the abolition of flogging, his motion was understood to be of that purport, and as such we then commented upon it\*.

Nay, Mr. Macauley reminded the gallant member that in moving for a select committee he had said: "I call upon the house to put an end to this brutal and barbarous torture. The practice necessary for maintaining the discipline of continental armies is not required for the British soldier; for he may be governed by more ennobling impulses than those of terror."

Lord A. Lennox observed in his speech that no further step towards the abolition of flogging could be taken, until the condition of the soldier, and especially his moral character, was improved. There are now four colonels in the army, who underwent corporal punishment, when privates. This is intended, of course, as a fact in favour of flogging. Lord A. Lennox meant to ask, how can you say that the lash is debasing, when it allows soldiers to

---

\* *MEDICAL GAZETTE*, March 31, 1838.

rise so high from the ranks' But the fact cuts both ways; for we might ask in reply, how can you say that it is necessary to use the lash with spirits so generous that they can soar from the station of a private to that of a colonel?

Mr. W. O. Stanley was convinced "that if flogging took place in the face of the public, not a month would elapse till such an outcry would be raised as must put an end to the practice."

This is a good practical observation; for there many things which to be hated need but to be seen. Nor was his concluding remark less pertinent. "In his opinion, much good had been done by discussion; for if the matter had been left in the hands of military men, flogging would have continued to this hour in full force."

Major Vivian thought that the former abuse of the power of flogging formed no argument against its legitimate use at the present day. Granted; but the former abuse, coupled with the former defences of that abuse, show clearly that nothing is too monstrous to find an advocate; and make us hope that the 200 lashes of the present system will in turn be forced to yield to the voice of reason and humanity.

The Major thinks Captain Bernal's motion unseasonable, particularly as the army is about to be increased.

We will conclude with noticing a single point in Colonel Rawdon's speech. He defended the sentence of a court-martial, of which he was president, by which a soldier was sentenced to 150 lashes. It may have been right to flog the man; but were not the lashes too many? Does it follow that because scourging is, under existing circumstances, an indispensable punishment, it is necessary to inflict it to the utmost verge of safety — until the surgeon, watching the fluttering pulse, gives notice that nature can bear no more?

If, in the Jewish commonwealth, in the early morning of civilization, 40 lashes were a sufficient maximum, why should ours be of five times that amount? Why must we go so far beyond the limits permitted in the Russian, Prussian, and Austrian armies? The truth is, that while generally advancing in the van of the continent, we have in this point retained more of the fierce and vindictive usages of the middle ages.

A French pamphleteer, having put forth a new *brochure*, asked Sir James Mackintosh his opinion of it. "Every thing that you say is very true," replied Sir James; "but in England we assume it all as data."

In this matter of military flogging, on the contrary, we are behind the average intelligence of the age; and the things which are assumed as data in favour of humanity by the despotic Austrian, and the barbarous Muscovite, must here be argued, as if they were the most subtle refinements of philanthropy.

---

## ROYAL MEDICAL & CHIRURGICAL SOCIETY.

DR. SEYMOUR IN THE CHAIR.

May 10, 1842.

---

*Peculiar symptoms affecting an entire family, and terminating in death.* By JOHN WILSON, M.D. Physician to the Middlesex Hospital.

It appears that the family, consisting of father, mother, and three children, were in good health up to the evening of December 30, 1840. On January 1, 1841, the father, Giovanni Arzoni, a Neapolitan, and manufacturer of colours, was taken ill with gripping pains and purging, which never ceased till death. He was sick at times, but never vomited; the motions were offensive and black; had frequent cold fits during the day, followed by much fever. The joints from the first were swollen, not red, but so painful that he could not be put into a warm bath. He was considered by the medical man who attended him to be labour-

ing under typhoid fever. He died on 20th January. On examination after death, the stomach was found healthy, but slightly discoloured in one part, attributable only to a natural cause: it contained a small quantity of fluid (homogeneous), principally animal matter. Intestines healthy. Lungs and pleura presented strong evidence of inflammation, *quite sufficient to account for death*. The youngest child, æt. 2 years, died on 16th January. On examination after death, there was no morbid condition of any of the viscera but the lungs, and they presented some little congestion only: the stomach and intestines were specially healthy. The above information was obtained from the evidence given at the coroner's inquest; the cases were not seen by the author. On the 26th Jan. the survivors, the mother and two children, were admitted into the Middlesex Hospital, under the care of Dr. Wilson. The mother, who was about four months advanced in pregnancy, was taken ill on the 2d Jan. with pain in her head, and sleeplessness during the night, and she lost her consciousness. The bowels were affected with severe pain, and there were frequent evacuations, sometimes only of foetid gas, at others of matter like putrid flesh. Three days after she lost the use of her limbs, and had pain in the joints. On the sixth day, oedema of the feet, legs, and thighs, came on, and the urine was scanty, high-coloured, and offensive: water flowed from the mouth, which "had a cankerous taste." On 15th March, she gave birth to a very small infant, which only lived 24 hours; she herself died on 21st March, labouring under symptoms of puerperal fever.

The details of this case, as well as the cases of the two children who also died in the hospital, are carefully related by the author, to which our limits oblige us to confine ourselves.

In all the three patients the most prominent features of their sufferings were the general soreness of the fleshy parts as well as of the joints, exquisite sensibility of the skin when touched, and the pain produced whenever they were moved or their position changed, according to their so frequently expressed wishes.

Next may be noticed the oedema, and particularly that of the inferior extremities, which was present in all the three; the alkaline state of the urine, when admitted, and their desire for acid drink; the faces of all being pale, haggard, and so care-worn as to give to the children the aspect of aged dwarfs, from their hollow cheeks, sharp features, exsanguined and emaciated bodies. At the same time their appetites were great; that of Mary Ann ravenous. But the mother's never was good; on the contrary, at times it was difficult to induce her to taste

even some trifling sustenance. The mother, at different times, was much exhausted by diarrhoea, and both the children suffered from it, but less severely. During their afflictions the intellects of all preserved their integrities; lastly, there was the "cankery" taste of the mother, the "metallic" taste of the boy, the watery state of the mouth and eyes, in each; the teasing, hacking, dry cough, common to all, and affecting the children particularly towards the last. Then their lying sometimes without any covering, even during the coldest season, when at nights the external atmosphere was 10 or 15 degrees below the freezing point, and their objecting to even a sheet, while their flesh was so greatly wasted, and their lungs became less and less capable of absorbing oxygen, from the gradual infiltration of blood into parts at their vesicular tissue, diminishing proportionally the respirable portions. The death of the mother was accelerated by parturition, and examination after death showed very extensive disease in both the abdomen and chest, yet probably differing considerably from what might have resulted had parturition not occurred, and had she died, like the children, of the affection common to all of them, and not been sooner carried off by a new disease supervening on the original one.

The abrasions or ulcerations of the sulci of the stomach of the children have been noticed; but they were so slight that, in ordinary cases, they might have been overlooked, without attention having been particularly directed to that organ. Neither the mucous membrane of the intestines, nor other parts of the abdominal viscera, showed any particular change from the normal state.

But the organ by which death finally entered appeared in these two to have been by the lungs; for the blood at last seemed infiltrated into their tissue, rendering portions of them dark, and so heavy as to sink in water, and resembling considerably the state of the lungs of those who died of the spotted fever in 1837, and which I have described in the MEDICAL GAZETTE as non-circumscribed pulmonary apoplexy, caused by the blood becoming so altered as to escape from its proper vessels into the tissue of the lungs, thus rendering portions of them (as in these) black, and so heavy as to sink in water. Yet these parts were not circumscribed by healthy lung, but they gradually shaded off from the heavy dark parts to the respirable portions.

The author abstains from giving any opinion as to the cause of these deaths.

After the admission of this part of the Arzoni family into the hospital, the coroner caused the bodies of the father and infant to be disinterred, and examined. A chemical analysis was made, and an inquest held; yet

no conclusive evidence resulted. So that legal, chemical, and medical investigations, combined, have not been able to unravel the mystery which envelops the cause of death.

Dr. Addison begged to ask the author what was the condition of the kidneys in these cases. As the paper had been read the conviction became constantly stronger in his mind that these were cases of scarlatina, of a kind not uncommon, in which the eruption either does not appear at all, or appears but for a short time and on a small part of the body, so that it may be easily overlooked. Reviewing all the symptoms described, and especially the acute oedema and other signs of dropsy, he should have expected that the kidneys would present some of those changes of aspect or of structure which, as far as he had seen, they always present in cases where dropsy supervenes after scarlet fever: such as increased vascularity, a change of colour, or some other distinct alteration.

Dr. Wilson said the kidneys were perfectly healthy in all the cases. As to the albumen which was present in the urine of one of them, he could not lay much stress on that as a sign of scarlatina, for he had constantly observed it in diseases where there was at least no permanent disease of the kidney. The eruption which was present bore no resemblance whatever to that of scarlet fever, and did not come out till late in the disease; nor, as far as he could tell, was there any characteristic sign of scarlet fever in any of the patients.

Dr. Merriman said that it was a strong argument against the existence of scarlet fever, that in no one of five cases was there any characteristic or well-marked eruption. It was certainly not rare to meet with isolated anomalous cases, where little or no eruption existed; but when scarlatina affected a whole family it was sure to show itself in a distinct form in one or more of the members: many might have the disease in an obscure manner, but at last it would appear in one with all its obvious characters, and leave no doubt of the nature of the affection in the others. That, however, had not occurred in the cases just read: in all, the symptoms were alike obscure.

The President (Dr. Seymour) was strongly inclined to refer the symptoms and the deaths of all those persons to the effects of poison. As the cases were read, he was forcibly struck with their resemblance to those related as the consequences of slow poisoning; more especially of that which was supposed to be employed so frequently in the 17th century. The circumstance of the man being a colour-maker, who it was very probable used some deleterious material

in his business, was very favourable to this view of the case. Many instances were well known, of poisons, such as that of lead for example, which, slowly introduced, and in small quantities at a time, produced an almost inexplicable series of symptoms, and sometimes death, affecting in succession, perhaps, every organ of the body. Altogether, the cases had the character of being produced by the repeated influence of small quantities of some deleterious substance, some mineral poison: and it was strongly against the notion of their resulting from any epidemic influence, that this one family was alone affected, and that the neighbourhood, and the other persons even in the same house, remained perfectly well.

Mr. J. Dalrymple, coinciding in this view, said, that it was probable the deleterious substance was some material which the man used in the manufacture of the ultra-marine, for which he was said to be celebrated. The genuine ultra-marine was calcined lapis lazuli, a very costly material, which there was every inducement to adulterate: and it was well known that nine-tenths of that which was sold as ultra-marine was spurious. He did not know what this man's secret of manufacture was, but he thought it very probable that the material which it was said he concealed from all his workmen was some poisonous salt which had, by accident or design, destroyed him and his family.

Dr. C. J. B. Williams suggested that it was some compound of arsenic. It was well known that the material commonly employed in the adulteration of ultra-marine was cobalt, a metal which, in its natural state, exists in combination with the ores of arsenic. There was, also, no one poison of which the effects were so anomalous, or exhibited so generally in all the tissues, as those of arsenic, which, in these respects, came more nearly to the character of the influence of malaria than any other substance known.

Dr. Truman suggested the improbability that the children should be poisoned by any material used in their father's trade, in which they were too young to have assisted.

Mr. Arnott said that these cases had, at the time of their occurrence, excited great interest at the Middlesex Hospital; and he, among others, had seen them. The first impression naturally was, that they were the result of the influence of poison, and the question of their being produced by the slow action of small and repeated doses of poison was then mooted; but to his mind such an explanation was rendered exceedingly improbable, by the fact that the symptoms had, in all the five cases, begun almost simultaneously, and were in all severe at the beginning.

Dr. Addison said that he also was about to use this same argument. What he had

heard did not move him from his first conclusion; the cases had, at first, all the characters of acute disease, and in their later progress all those of the sequelæ of acute disease. He therefore still thought it probable that they were instances of obscure scarlet fever; and he believed no deduction could be drawn from the disease being limited to a single house, for he had known this to occur in cases of genuine scarlet fever, which had remained limited to a single house for several months, all the individuals being successively, and some of them repeatedly, attacked by it.

In answer to a question from the President, Dr. Wilson said there was no probability of malaria or any noxious influence existing in the air of the apartments in which the people lived: they lived, in fact, in considerable comfort, in well-aired and well-furnished rooms; for the man made a considerable sum by a very profitable business.

*A case in which Pregnancy was unattended with the usual signs, and in which parturition occurred without labour-pains—rupture of the funis, which remained untied forty-five minutes.* By THOMAS LEWIS, Esq. Liverpool. [Communicated by Dr. C. J. B. Williams.]

The case was that of a lady, æt. 41, who had noticed an enlargement of abdomen for six or seven months. She felt certain she was not pregnant, because she had not experienced symptoms similar to those of her first pregnancy. Catamenia appeared last, eight or nine months ago. External examination not proving satisfactory, examination *per vaginam* was made, which disclosed the nature of the case. The os uteri was dilated to the size of a shilling, the neck entirely expanded, and the membranes and child's head could be felt. Though informed she was pregnant, she was sceptical, and made no preparation for the event.

On January 5th the author was sent for, and found the child born before his arrival: the funis was ruptured about four inches from the umbilicus. It appears the lady had suffered from diarrhoea for two days previous. At one o'clock A.M. she awoke, she says, with griping pains in the belly: these continued until six, when she got out of bed for ease. She walked into an adjoining room, and bending herself, rested her hands on a table. Suddenly the waters broke, and the child was expelled, and fell on the floor. She states positively she had no pain in the loins, nor bearing-down pains, previous to the expulsion of the child. The author considers the following facts established by the case:—

1. That pregnancy may occur, and nearly

reach its termination, without many of the ordinary signs.

2. That the arteries may contract, like other hollow muscular organs, without the consciousness of the mother.

3. That rupture of the funis is attended with little or no bleeding.

The practical doctrine he infers from it is, that in cases of illegitimate births occurring suddenly, and where the child is found dead, the circumstances should be of a very decided character before the guilt of infanticide be fixed on the mother.

## MEDICAL AID SOCIETY.

### HANDSOME REMUNERATION!

*To the Editor of the Medical Gazette.*

SIR,

WITH this I beg to forward you the purport of a handbill publicly exhibited a short time since on the walls of this place, and the Society (of which it was the advertisement) is now in full operation, midwifery having been recently accepted by its medical officer, in addition to his already arduous duties, without any increase in the proposed scale of remuneration.

Hitherto the profession in Macclesfield have stood respectably: medical ethics have been adhered to, the dignity of the calling supported, and beyond quackery, and the practices of a host of the *unlicensed*, it has had little to disturb the repose of its position. But this scheme of supplying cheap medicine, &c. although established avowedly for the benefit of the poor, appears now to have no limit: already many shopkeepers, and others of a like grade (who aforesaid cheerfully paid their medical attendant the customary fees), have been admitted, and a steady canvass is still proceeding, *volens volens*, to induce others to become members. Sooner or later this must affect the pockets of the other practitioners, as well as their standing and reputation with the public; and in vain have they almost unanimously protested against this beggarly competition. There is a public dispensary and Union doctor in full operation in this town, and it will avail little that the legislature protects us against empirics, whilst we have amongst ourselves (and in this instance the partner of one of the oldest and most respectable practitioners in the town) those who do not scruple to hire themselves on terms at once degrading and unprofessional. What is to be done in this case? To scout a man who can so far demean himself and his profession I fear would make but a sorry impression. If you think an exposure of this in the pages of your excellent journal will be

of any service, you will use it accordingly, or if otherwise you can suggest a better mode of proceeding in reference to this case, you will equally oblige

Your obedient servant,  
A CONSTANT READER AND  
SUBSCRIBER.

May 2, 1842.

" MACCLESFIELD MEDICAL AID SOCIETY.

" J. TURNER, Esq. Park Green, Surgeon  
to the Society.

" The inhabitants of Macclesfield and its vicinity are respectfully informed that a Society is being organized, which, for a small weekly subscription, proposes to insure to its members the benefits of medical attendance and medicine in cases of sickness" [and now of midwifery].

" This Society admits families of all ages in sickness and in health, residing within two and a half miles of the Macclesfield Sunday School.

" The terms are one halfpenny per week for all above twelve years of age; and under that age every three are taken for that sum. Entrance one penny. Any female member paying sixpence on or before the birth of any of her children, such children shall become full members from the date of their birth. All persons paying one month's subscription in addition to the entrance fee, on or before the 1st of January, 1842, shall be full members, and entitled *to all the benefits of the Society.*"

#### THE PUFF DIRECT.

*To the Editor of the Medical Gazette.*

SIR,

IN the Reading Mercury, of the 7th inst., appears the following paragraph, which need only be noticed to elicit that contempt from the profession which it merits. It is a matter of regret that men should enter the profession whose ideas of professional etiquette and propriety are so loose, and whose merits are so hidden, as to require public attention to be called to one successful case. It leads us to suspect it to be the only one. No such paragraph ought to have been admitted, unless with the sanction of Mr. Bulley.

" William Thresher, late a patient in the Royal Berks Hospital, was, three years previous to his admission to that institution, unable to move without crutches. Feeling deeply sensible of the benefits he has received, he begs to tender his thanks for the same, more particularly to Mr. F. A. Bulley, through whose care, by the blessing of Almighty God, he is now enabled to walk without any assistance."

Hoping that you may consider the subject worthy of your consideration, I beg to sign myself

Your obedient servant,  
AMICUS.

London, May 9, 1842.

#### INJECTION OF AIR INTO THE EUSTACHIAN TUBE.

*To the Editor of the Medical Gazette.*

SIR,

IN your publication, of the 6th May, at page 59, I find that an anonymous correspondent imputes to me "an exertion of mechanical ingenuity" which I never made; and adds, that "I consider that I have overcome a difficulty" which I certainly never combated.

If it were conceivable that a person, calling himself a medical man, could be so ignorant of the plainest principles of pneumatics as to mistake an apparatus operating by dilatation for one for effecting condensation, I should not presume to infer that your correspondent cannot have read the report he refers to, otherwise he would not have made so unfounded an assertion, nor have taken so uncourteous a liberty with the name of a person of whom he knows nothing.

The very simple apparatus, which an accidental circumstance led me to suggest to Dr. Turnbull, being sufficiently described in Chambers' Journal (the report which I imagine Medicus refers to), I shall not trouble you with any account of the "exertion," nor of the effects of its application; and shall only add, that, however much he may doubt the veracity or the power of observation of the numerous persons who have benefitted by it, he will find, if he make his inquiry in a candid spirit, that the mass of evidence will be still more "incontrollable" than the get of condensed air from Kramer's machine, of which he so forcibly expresses his disapprobation.—I am sir,

Your obedient servant,  
JOHN ROBISON.

Edinburgh, May 9, 1842.

#### ATTENDANCE ON THE POOR.

*To the Editor of the Medical Gazette.*

SIR,

IN your GAZETTE, dated 6th May, a gentleman, signing himself M.D. in an article entitled "Attendance on the Poor," states that, "in the eye of the law, a physician or surgeon is not duly licensed to practise as a medical man;" and in substantiation of this assertion, remarks, that he "believes it has been decided, in several cases, that neither

the surgeon nor physician can act as an apothecary, unless he also possesses the requisite license."

It appears to me that M.D. is attaching a different meaning to the words *medical man* to what the more enlightened portion of society is accustomed to do, whatever may be the vulgar usage of the word. If in the "4th & 5th Will. 1, cap. 76," it is definitely stated that *apothecary* and *medical man* are used as synonyms, then, in concert with M.D., I am inclined to entertain doubts of the legality of the recent medical regulations; if not, I fancy them to be perfectly legal.

If you can find room for these remarks, I shall feel obliged.—I am, sir,

Your obedient servant,

M.R.C.S.L.

Jesus College, Cambridge.

May 1, 1842.

#### A LETTER ON THE COLD WATER TREATMENT OF PRISSNITZ AT GRAFFENBERG.

As the cold water treatment at Graffenberg by Prissnitz has excited so much interest, we think the following extract from the letter of a gentleman who was a patient there in June last, may be acceptable to our readers:—

"It requires great patience and perseverance to go through the cold water cure, and it is decidedly the most discouraging of any other. I shall now give you an exact account of what I have to go through every day, as well as all other persons who are able to bear it. The attendant comes into my room at 5 A.M. with a wet sheet as cold as ice. I get up, while he puts a large thick blanket on the bed over which he lays the sheet, which I have to stretch myself on, when he wraps it close all about me, and then regularly packs me up, so that I am unable to stir a limb, and then puts a soft down bed over all. I remain in that enviable state for one hour: my first impression was that I should be perished to death, but in about

fteen minutes I was in a most comfortable heat, and generally slept until 6 o'clock, when the man enters and unpacks me, taking the sheet away, leaving the blanket close about me, when I then go to the bath room, which is situated but a few steps from my bed-room, when I plunge in head and heels. I am then well dried, and after being dressed, I set out to walk until 8 o'clock, when I go to breakfast, first taking three or four tumblers of cold water, and about six more before night. Fancy about three hundred persons from all nations sitting down to breakfast on bread, butter, and milk, there being no tea or coffee allowed; we have also abundance of strawberries, so that I assure you we all feel perfectly content, and enjoy

it much: at 10 o'clock I must be in my room to undress and take a douche bath, which at first I did not get enamoured with. The water is conveyed in wooden pipes from the mountain, and is as cold as possible. When that is over, and I am dressed, I have but a short time to walk, as I must be in my room again at half-past 11 o'clock, where a sitz bath is brought in, where I remain sitting for twenty minutes, after which I have until 1 o'clock to amuse myself in the best way I can, when the dinner bell rings, and we all congregate as we did in the morning. The room is a very fine one, being 120 feet long by 50 broad, and capable of dining 500 persons, which number and more are here under cure, but a great many stop at Frywalden, a small and neat town one mile distant, and where Prissnitz goes twice a day to visit his patients. You would suppose I had the remainder of the day to myself, but not so, for at 5 o'clock I must again go into the wet sheet, and take the bath after, as in the morning. We meet at 8 to supper, which consists of the same fare as at breakfast; I am generally in bed by ten, but not before the man comes in with two long wet linen bandages, which he puts round my waist, and at the back of the neck, and between my shoulders, by way of making me comfortable for the night. You can fancy, from the above how I am to pass my days here, that I have not much idle time on my hands. I did not mention that, in addition, I have to swallow from twelve to fifteen tumblers of cold water. Graffenberg is a very high hill in the centre of three valleys, and, what makes it very picturesque, it is all finely wooded at the top, and walks made all through, and on the sides, with numerous seats of all dimensions, placed for the company: and an amateur band comes from Frywalden twice a week to play, and on every Sunday there is a full band that plays all the time we are at dinner, and again after supper, when such as are inclined commence dancing."—*Dub. Journ. of Med. Science.*

#### OSSIFIC DEPOSITS IN THE ARTERIAL SYSTEM.—GANGRENE OF THE FEET.

MR. HAMILTON exhibited the recent parts in this case, the subject of which had arrived at the advanced age of 101. In the aorta, there were several bony plates between the internal and middle coats; in some places the internal coat had been destroyed, and the bony plates projected into the cavity of the vessel; the osseous deposits were most abundant at the bifurcation of the arterial trunks. Examples of this were shown in the celiac axis, and in the arteries of the upper extremities. Mr. Hamilton pointed out the diseased condition of the subclavian,

vertebral, and coronary arteries. The subject of the case was a dairyman, named James Stewart, who was attacked with gangrene of the toes about seventeen days before death. Mr. Hamilton saw him on the fifth day. The toes, as represented in the drawing, which Mr. Hamilton exhibited, were black, dry, and shrivelled, and the integuments beyond the sphacelated parts were of a dark chocolate colour. An attempt was made by nature to arrest the gangrene, but it failed, and the disease continued to spread until a few days before death. The dorsum of the foot was pale and cold, and stripped of epidermis to a considerable extent; on the sole there were several livid vesicles filled with serum: there was very little pain, but the tenderness on pressure was very great. The man sunk gradually, and died on the seventeenth day from the first appearance of the disease. Mr. Hamilton observed that Pott, who first described this affection, appeared to be ignorant of its true pathology; for he denies that an ossified state of the vessels is the cause of the disease. The researches, however, of Cruveilhier and Carswell have proved that an ossified condition of the vessels is one of the most frequent causes of the disease, and that in most cases of the kind the arterial branches are found to be more or less engaged. In some of these cases the progress of the morbid change can be very satisfactorily traced. In addition to ossification of the artery, and disease of its internal coat, the latter is very often absorbed at various points, the bony spiculae project into the cavity of the vessel, and around these projections the fibrin of the blood coagulates, giving rise to a gradual obstruction and ultimate closure of the affected tube. This afforded some explanation of the way in which the arteries were plugged up, but would not account for the absence of circulation in the foot, unless the smaller vessels were also obstructed, which actually was the case. Mr. Hamilton showed one of Carswell's plates, in which the same appearances were observed as in the preparation which he had laid before the Society. In the plate were seen several bony spiculae projecting into the cavity of the vessel, round which deposits of fibrin had taken place. In Stewart's case, Mr. Hamilton observed that in tracing down the femoral artery the same changes would be seen as he had previously pointed out in the aorta. In some parts the coats of the vessels were greatly thickened; in others studded with bony plates, and the whole artery felt like a hard cord, its cavity being narrowed so as barely to admit the end of a straw at the upper part. Lower down, the calibre of the vessel was still farther reduced, and the popliteal, immediately before it divides into the tibial and

peroneal, was completely obstructed. The opposite femoral artery exhibited similar changes. A curious fact connected with this case was, that in both extremities, the peroneal and anterior tibial arteries were both longer than the posterior tibial, and it was remarkable that the same condition has been delineated by Cruveilhier; in both extremities the arterial trunks were obstructed from the ham down to the toes. Evident traces of the same morbid process, but not amounting to obstruction, were to be seen in the innominate, subclavian, carotid, and vertebral arteries, all of which presented thickening and erosion of the internal coat, with small deposits of bony matter, the disease being chiefly seated at the point where the trunk of the vessel divided into branches. The patient in this case had gangrene of both feet. His pulse was about 104, and very feeble.—*Dub. Journ. of Med. Science.*

## FRACTURE OF THE NECK OF THE FEMUR,

### WITH CHRONIC RHEUMATIC ARTHRITIS.

MR. SMITH presented a specimen of fracture of the neck of the femur, occurring in a person aged sixty-six, who had been subject to chronic rheumatic arthritis. Mr. Smith said that he had very seldom met with cases of the coexistence of this disease with fracture of the neck of the femur within the capsular ligament. The present case, however, was one of this description. The shortening of the limb did not amount to an inch, and the eversion of the foot did not appear so well marked as it usually is: the two fragments being interlocked in each other so as to prevent eversion of the foot. The fibro-synovial folds were torn across completely on the anterior surface; but posteriorly they were perfect. Mr. Smith said that the reason of this was, that when the neck of the bone is broken, the shaft being rotated outwards, stretches, the anterior part of these folds while the posterior part is relaxed; in fact, the rotation outwards approximates the intertrochanteric line to the base of the head of the bone. Hence the front is usually torn, while the posterior portion remains intact. As to the arthritis, one of the principal effects of it was an ivory deposit on the head of the bone. The disease in this case presented one peculiarity, namely, that the ligamentum teres had not entirely disappeared; it was, however, unravelled in its texture, and reduced to a few shreds. Mr. Smith observed, that it was rather rare to meet with the coexistence of fracture of the neck of the femur with chronic rheumatic arthritis. He could not say what was the reason of this; perhaps it was from the inability of the patient to walk, which might render him more cautious, and consequently less liable to acci-

dent, or, perhaps, from the partial absorption of the cervix femoris, the head and shaft of the bone were brought into closer approximation. This, perhaps, might account for the rare occurrence of fracture of the neck of the femur in cases of chronic rheumatic arthritis. Mr. Smith also exhibited a specimen of complete absorption of the neck of the bone in this disease, in which the head had sunk below the level of the trochanter major. — *Dub. Journ. of Medical Science*.

## CURIOUS

## CASE OF CHRONIC PLEURITIS

## WITH OSSIFICATION OF THE DIAPHRAGM.

KOHUN, a convict, was admitted to the gaol here upon the 8th Dec. 1838, and died 13th March 1839: he did not wish to go into hospital, but was ordered to be put under medical treatment by me, as he appeared to be very sickly, much emaciated, and unable to labour. On admission, his pulse, tongue, skin, &c. were quite natural, and his appetite was very good. The most remarkable feature in the case was, that his voice was quite weak, and he could only speak in a gentle whisper, even when he endeavoured to speak as loud as possible: he said that he had lost his voice two years ago, and he could not tell how: he stated that debility was his only complaint. The native doctor informed me that this man had been often in hospital during the last two years with fever, but no mention was made of cough or disease in the lungs; the lower part of the right thoracic cavity was examined, and on percussion was very dull. As no disease could be discovered, he had little or no treatment till seven weeks before he died, when I found out that he had a slight cough, which soon became troublesome, and was accompanied by acute pain in the lower right thorax, where the sound was so dull on percussion. On the application of the stethoscope the respiratory murmur could not be heard. The pulse was quite natural to the last. He was treated by repeated applications of leeches and blisters to the pained part; the usual inward remedies were also administered, but debility increased daily, and some anasarca came on before death.

*Sectio Cadaveris*, 13th March, 1839.—

Thorax: On being laid open much disease was observed on its right side: close to the sternum a perfect cavity was formed by a strong false membrane, which contained some four or six ounces of serum: the inner coat of this bag was soft, and like jelly, but the outer was strong and thick. On attempting to remove the right lung, the adhesions of the pleura costalis and pulmonalis were so strong that they could not be sepa-

rated, and the lung was brought out piecemeal; to a considerable extent it was found in a hepatised state, and sank in water.—  
Diaphragm: The portion of this muscle situated between the liver and right lung was found ossified to a considerable extent; so much so that it was a difficult thing to remove or cut it with a knife. Liver was much enlarged, and engorged with blood.

REMARKS.—The perfect ossification of a considerable part of the greater muscle of the diaphragm appears to have been the loss of voice in this case, expiration being performed so slowly that the air could not act with force on the organs of voice. The pulse never rose above the natural standard, and the appetite was keen to the last. The throat was also examined, but no disease could be detected.—*Indian Journ. of Med. Science*.

## LIST OF PRIZE-MEN

*At the different Medical Schools of London\*.*

## ST. BARTHOLOMEW'S HOSPITAL MEDICAL SCHOOL.

Thursday, May 5, 1842.

*Medicine*.—First prize, T. J. Austin, London; second prize, Henry Mitchell, Cambridge.

*Clinical Medicine*.—Prize, Henry Mitchell, Cambridge.

*Surgery*.—First prize, John Henry Wise, Banbury; second prize, Benjamin Lever, Culworth; third prize, James H. Coveney, Stilton.

*Clinical Surgery*.—Prize, Benjamin Lever, Culworth.

*Anatomy and Physiology*.—First prize, Charles Robinson, Bradford, Wilts; second prize, Edward Dewes, Coventry; third prize, William Pollard, Plympton, Devon. Honorary certificates, James H. Coveney, Stilton; W. S. Kirkes, Moorlands, Lancashire; and G. Saunders, Newfoundland.

*Materia Medica*.—Prize, Thomas R. Evans, Lynn, Norfolk.

*Chemistry*.—First prize, W. S. Kirkes, Moorlands, Lancashire; second prize, Josiah Blomfield, London. Honorary certificates, J. M. Girdlestone, Rainthorpe, Norfolk; and J. Phillips, Redruth, Cornwall.

*Midwifery*.—First prize, John Henry Wise, Banbury; second prize, B. Lever, Culworth. Honorary certificates, H. Mitchell, Cambridge; and Jas. H. Coveney, Stilton.

*Practical Midwifery*.—Prize, Thomas Taylor, Witney, Oxford. Honorary certificate, John Henry Wise, Banbury.

*Botany*.—First prize, John Henry Wise, Banbury; second prize, Thomas J. Austin, London.

\* We have arranged them alphabetically.

*Forensic Medicine.*—Prize, William Martindale, London.

CHARING-CROSS HOSPITAL MEDICAL SCHOOL.

The Rev. G. H. BOWERS, B.D. Treasurer of the Hospital in the chair.

*Botany.*—Silver medal, R. C. Golding, London; certificate, Elisha Noyce.

*Midwifery.*—R. C. Golding.

WINTER SESSION, 1841-2.

*Exhibition of £15. per Annum.*—John Terry, Bath.

*Medicine.*—Michael Teevan, Princes Row, Kennington.

*Surgery.*—Senior class, first prize, John Moore, Wickham Market, Suffolk; second prize, Arthur Taylor, Nether Crawley, Luton, Beds. Junior class, first prize, J. Terry; second prize, W. M. Neale, Walworth.

*Midwifery.*—Senior classes, students of two sessions, 1, M. Teevan; 2, R. C. Golding. Students of one session, 1, John Moore; 2, W. M. Neale. Junior class, T. F. May, Butcher Row, Ratcliffe Cross.

*Physiology.*—Senior class, equal, R. C. Golding, John Moore. Junior class, E. Noyce.

*Practical Anatomy.*—Senior class, first prize, James Yate, Madeley, Salop; second prize, John Moore. Junior class, first prize, J. Terry; second prize, G. F. Burroughs, Shepton Mallet.

*Chemistry.*—First prize, E. Noyce; second prize, W. Ackland, Stawell, Somerset.

*Materia Medica.*—First prize, M. Teevan; second prize, E. Noyce.

*Diligence and Good Conduct.*—First prize, J. Terry; second prize, G. F. Burroughs.

GUY'S HOSPITAL MEDICAL SCHOOL.

Saturday, May 7, 1842.

Dr. BRIGHT, F.R.S. in the chair.

*Medicine.*—First prize (gold medal), J. Vincent, Bedford; second prize (silver do.), J. H. Browne, Southton.

*Materia Medica.*—Second prize (silver medal), H. J. Fotherby, London. Certificate, J. F. Wills, Crewkerne.

*Chemistry.*—First prize (books), George Ayton, Kenilworth. Certificates, T. P. Ramskill, Clapham; J. C. Fotherby, London; J. C. Forster, London.

*Practical Chemistry.*—Prize, Edward Garraway, Feversham.

*Anatomy: Senior Division.*—Equal prizes (instruments), H. M. Webb, Barnstaple; H. W. Watson, Newcastle.

*Junior Division.*—Equal prizes (instruments), J. T. Caddy, Bideford; H. A. Oldfield, London. Certificate, C. E. Pratt, Appledore.

*Pathological Anatomy.*—Prize (silver medal), W. W. Kershaw, Clapham.

*Surgery.*—First prize (instruments), C. A. Aiken, London. Certificates, H. W. Watson, Newcastle; P. W. Thompson, Brentford.

*Ophthalmic Surgery.*—Prize (silver medal), Caleb Rose, Swaffham.

*Midwifery: Senior Division.*—First prize (instruments), Caleb Rose, Swaffham. Certificate, Mr. A. C. Ayres, Ramsgate.

*Midwifery: Junior Division.*—Prize (instruments), James Vincent, Bedford. Certificate, Mr. H. W. Watson, Newcastle.

*Practical Midwifery.*—Certificates, Martindale Ward, Reading; W. H. Pettigrew, Woolwich.

*Botany.*—Equal Prizes (books), H. M. Webb, Barnstaple; Geo. Ayton, Kenilworth.

*Medical Jurisprudence.*—Prize (books), Walter Clegg, London. Certificates, J. Mills, Exeter; Mr. W. Chapman, Tooting.

*Medical Physics.*—Prize (silver medal). J. N. Watson, Newcastle.

The diploma of the Physical Society granted to Drs. E. L. Birkett, D. J. T. Francis, and J. B. Nevins; and Messrs. J. R. Bedford and J. C. Parrott.

*Clinical Report Society.*—Medical certificate, — Browne, Southton; surgical certificate, Alfred Poland, London.

*Pupils' Physical Society.*—Prize (instruments), Walter Clegg, London.—This prize is awarded for the best essay on a given subject.

KING'S COLLEGE MEDICAL SCHOOL.

Friday, May 6, 1842.

The Lord Archbishop of CANTERBURY in the chair.

*Medical Scholarship (£40 a-year).*—Scholar elected, Mr. George Johnson; prize to Mr. Inman.

*DIVISION I.—Medicine, Surgery, and Midwifery.*—First prize, George Johnson; second prize, John Percival. Certificates of honour: Henry J. Hunter, Robert W. Woolcombe, J. G. Grylls.

*DIVISION II.—Materia Medica and Physiology.*—First prize, William Henry Parsey; second prize, Alfred B. Andrews. Certificates of honour: S. A. Steele, Thomas Hawksley.

*DIVISION III.—Anatomy and Chemistry.*—Second prize, B. L. Jemmet. Certificates of honour: Caleb Barrett, R. Roberts.

*Botany.*—Prize, John Baxter Langley. Certificates of honour: M. S. Todd, J. H. Blount, S. H. Steele, H. S. Lyford.

*Forensic Medicine.*—Prize, R. P. Dodd. Certificates of honour: John Percival, Evan Thomas, C. W. Mann.

*Comparative Anatomy.*—Prize, Alfred C. Barker.

**Medical Society's Prizes.**—First prize, George Johnson; second prize, John Baxter Langley.

**Warneford Prizes.**—First prize (gold medal, value £10, and books value £15), George Johnson; second prize (gold medal, value £5, and books value £10), George P. Atkinson.

**Leathes' Prizes.**—First prize (quarto Bible), Frederick J. Hensley; second prize (quarto Prayer-book), Boughton Kingdon.

**Medical Associates.**—George Johnson, Boughton Kingdon.

MIDDLESEX HOSPITAL MEDICAL SCHOOL.

Thursday, April 21, 1842.

JAMES ARNOTT, Esq. in the chair.

**Anatomy.**—Prize, C. E. Hatherly. Certificate, John Crawley.

**Physiology.**—First prize, Henry Greaves; second prize, Thomas Graham. Certificate, W. Hoblyn.

**Practical Anatomy.**—First prize, T. S. Smyth; second prize, C. W. Smith. Certificates, A. Peat and — Broadbent.

**Practice of Medicine.**—First prize, T. Graham; second prize, — Nisbit; third prize, — Baker. Certificates, — Walker and W. Hoblyn.

**Surgery.**—Prize, A. Peat. Certificate, T. S. Smyth.

**Midwifery.**—First prize, R. D. Ward; second prize, T. S. Rising. Certificates, — Baker and — Walker.

**Chemistry.**—First prize, C. R. Morgan. Certificate, J. Stephens.

**Materia Medica.**—Prize, C. R. Morgan. Certificate, J. Stephens.

**Forensic Medicine.**—Prize, H. Greaves. Certificate, — Taylor.

**Botany.**—Prize, Charles R. Francis. Certificate, Thomas Rising.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL.

Monday, April 25, 1842.

MR. SERJEANT THOMPSON in the chair.

**Clinical Medicine.**—Prize, Robert Webb Watkins. Honorary certificate, Samuel Hallet Griffith.

**Clinical Surgery.**—Prize, Robert Barnes.

**Practice of Physic.**—Prize, Edward Bullock. Honorary certificate, Robt. Frith Jarvis.

**Surgery.**—James Dunn.

**Materia Medica.**—Prize, William Spackman. Hon. certificate, Walter Haldenby.

**Anatomy.**—Senior prize, George Sayle. Honorary certificate, A. G. Field.

Junior prize, Thomas Clark. Honorary certificate, — Kingsley.

**Midwifery.**—Prizes, Robert Frith Jarvis and Henry William Fuller. Honorary certificates, John Baber, S. H. Griffith, and Edward Tegart.

**Botany.**—First prize, S. H. Griffith; second prize, F. S. Tate. Honorary certificate, — Griffin.

UNIVERSITY COLLEGE MEDICAL SCHOOL.

Saturday, April 30, 1842.

The Right Hon. Lord CAMPBELL presided.

**Anatomy and Physiology.**—Gold medal, Henry Fearnside, of Otley, near Leeds; silver medals, equal, George Y. Heath, Henry James Stokes, of London.

**Midwifery.**—Gold medal, William John Preston, of London; first silver medal, A. B. Garrod, of Ipswich; second silver medal, Edwin Hearne, of Taunton.

**Chemistry.**—Gold medal, B. A. Harling, of Chester; first silver medal, Thomas Humphreys, of Anglesey; second silver medal, W. Brown, of Altarnun, Cornwall; prize essay, first medal, Richard Tudor, of London; ditto, second medal, Richard Worsley, of Blandford.

**Anatomy.**—Gold medal, H. Fearnside; first silver medal, Edwin Hearne; second silver medal, J. Thompson, of Launceston; junior class silver medal, Alfred Jackson, of London.

**Comparative Anatomy.**—Gold medal, T. P. Matthew, of London.

**Materia Medica.**—Gold medal, R. D. Harling, of Chester; first silver medal, R. Worsley; second silver medal, W. Edwards, of Carephilly.

**Surgery.**—Gold medal, Edwin Hearne; first silver medal, J. Topham, of Droitwich; second silver medal, Leonard Buckell, of Chichester.

**Medicine.**—Gold medal, A. B. Garrod; first silver medal, P. H. Williams, of Wem; second silver medal, H. Allen, of Macclesfield.

**Fellowes' Clinical Medals.**—Gold medal, C. J. Hare, M.B. Cantab. of Leeds; silver medal, Thomas Leonard, of London.

SUMMER TERM, 1841.

**Botany.**—Gold medal, W. J. Preston; silver medals, equal, J. E. Stocks, of Hull, and J. D. Heaton, of Leeds.

**Medical Jurisprudence.**—Prize, A. B. Garrod.

**Fellowes' Clinical Medal.**—J. D. Heaton.

WESTMINSTER HOSPITAL MEDICAL SCHOOL.

**Anatomy.**—First prize, Duncan Maclure, London; second do. Samuel Probyn, Monmouthshire; third do. Benjamin Longmore, London; fourth do. John Welch, Taunton; fifth do. Peter Clarke, Scotland.

**Physiology.**—S. Probyn, Monmouthshire.

**Materia Medica.**—First certificate, Sam. Probyn, Monmouthshire.

**Chemistry.**—First certificate, S. Probyn, Monmouthshire.

## PRESENTATION OF PLATE.

THE Committee of Officers of the Medical Department of the Army, appointed for the purpose of expressing to Mr. Guthrie their sense of the kindness and liberality with which he had placed his lectures and hospital instructions at their service for many years, delivered to him on Tuesday, the 10th of May, a service bearing the following inscription:—"To G. J. Guthrie, Esq. F.R.S. &c. &c. &c. this service of plate has been presented by three hundred officers of the medical department of the army, the companions of his early military services, or the pupils of his instruction. They desire to record by it their high sense of his liberal and distinguished conduct on every occasion, as well as to express their sincere affection and esteem."

## ROYAL COLLEGE OF SURGEONS.

## LIST OF GENTLEMEN ADMITTED MEMBERS.

*Monday, May 9, 1842.*

W. H. Carnegie.—S. N. Elliott.—H. Baillie.—W. Baillie.—J. Mills.—A. H. Godby.—J. H. Reynett.—R. D. Ward.—H. Gaskell.—H. Woodward.—J. Teare.—W. Murdock.

*Friday, May 13, 1842.*

J. T. La Presle.—A. Tulk.—C. Rose.—C. E. Prior.—R. Tilton.—J. W. Long.—W. Jollie.—A. M. Moger.—H. Hamilton.—J. H. Thornhill.

LECTURES  
ON THE  
PRINCIPLES AND PRACTICE OF  
PHYSIC.

*Delivered at King's College, London,*

BY DR. WATSON.

*Diseases of the liver. Acute inflammation. Abscess of the liver. Causes and treatment of acute hepatitis. Chronic hepatitis. Jaundice. Its symptoms, causes, and species.*

FROM the alimentary canal I go to the other organs directly or indirectly connected with the digestion and assimilation of our food. And, first, let us look at that large gland, the liver, of which the main office, as far as we can perceive, is the secretion of bile.

The liver is liable to various forms of disease: but it is not so frequently in fault as many would have us believe. It is often blamed most gratuitously and unjustly.

The researches of Mr. Kiernan, recently published in the Philosophical Transactions, have paved the way for a better understanding in future of its pathology. If I did not feel myself too much circumscribed by the remaining limits of this course of lectures, I should be glad to attempt to assist you in construing Mr. Kiernan's somewhat difficult, and very valuable paper. But doubtless you are made familiar with the anatomy of the organ, as described by him, in other lectures: and I must content myself with noticing, as we go along, one or two points, in respect to its morbid appearances, concerning which, before Mr. Kiernan took the subject up, great mistakes prevailed, even among the most celebrated pathologists.

I shall follow the usual order, and consider first, *inflammation* of the liver, which may be either acute or chronic.

These are, both of them, diseases that are much more common in warm climates than here.

756.—xxx.

Of well-marked acute hepatitis the symptoms are fever, with pain and a sense of tension in the right hypochondrium, inability to lie on the left side, difficulty of breathing, a dry cough, vomiting, hiccup.

You will not find all these symptoms present in every case: yet they are all worth attending to.

The pain is sometimes sharp and pricking, like a pleuritic stitch: sometimes dull and tensive. In the former case the peritoneal covering of the gland is supposed to be affected; in the latter its parenchyma. The pain sometimes extends to the right clavicle and to the top of the right shoulder. This circumstance was noticed by Hippocrates; and I have referred to it before as a good example of what are called sympathetic sensations. The existence of this pain makes it probable that the inflammation affects the convex surface of the liver. Occasionally the *left* shoulder is painful: the left lobe of the liver being involved in the disease. The pain in the right side is aggravated, often, by the movements of the diaphragm in respiration; and this explains the embarrassment of the breathing, and the short dry cough. Why the patient cannot well lie on the left side is obvious enough: all the connexions of the inflamed organ are then put upon the stretch by its weight. There are, however, some exceptions to this rule. On the under or concave part of the liver lies the pyloric extremity of the stomach; and that viscus often sympathizes with the hepatic inflammation: nausea and vomiting occur; and hiccup. The thoracic symptoms on the one hand, or the stomach symptoms on the other, may be expected to predominate, according as the convex or the concave surface of the organ is chiefly the seat of the inflammation.

The situation of the pain, the cough, the short and shallow breathing, used to puzzle the older observers: and they confess their occasional inability to determine whether the inflammation was situated in the lower lobe

of the right *lung*, or in the *liver*. But now-a-days we need have no difficulty in making the diagnosis. The ear will tell us, if we employ auscultation and percussion, whether the contents of the chest or of the belly are suffering: and my own experience has taught me that sharp pain, with feverishness, occurring in the debateable ground of the right side, denotes pleuritic inflammation far more often than it denotes hepatic.

*Jaundice* is an *occasional*, but by no means a *necessary* effect or accompaniment of hepatitis; whether acute or chronic: and, therefore, what I have to say of that symptom I shall give under a separate head.

Acute hepatitis may terminate in resolution; or it may terminate in diffused suppuration; or, what is more usual, in the formation of a circumscribed abscess, or of abscesses, in the liver. We do not often meet with hepatic abscesses in this climate; but they are very common in hot countries: and some of the most interesting events of the disease have relation to the progress of these collections of matter. When they approach the surface of the liver, adhesions generally take place (in virtue of that conservative principle of which we so constantly discern the working) between the diseased organ and the neighbouring parts. If no such adhesion occurred, the matter would at length burst into the cavity of the peritoneum; and this *does* sometimes happen. The peritonitis which is thus, suddenly, set up, is almost always fatal. I referred, however, in a former lecture to one instance in which it was recovered from. Sometimes the adhesion is effected between the liver and the parietes of the abdomen, and the abscess points *externally*, and may be opened by the surgeon. Such a case occurred in my neighbourhood last year. Sometimes the liver glues itself to the stomach, or to the intestines; and then the abscess breaks into the alimentary tube, the matter is evacuated by vomiting, or by stool: and all goes on tolerably well again. In other cases the agglutination is to the diaphragm, which is perforated, and the pus makes its way into the sac of the pleura, or through the lung to the bronchi, and so out by the mouth. I have seen three examples of this myself. In one the abscess originated in the formation and degeneration of hydatids in the liver; and the patient (a woman, she was under Dr. Macmichael's care in the Middlesex Hospital) spat up quantities of yellow fluid, consisting partly I suppose of pus, but chiefly of pure bile. The examination of the dead body ultimately demonstrated the nature of that case. The second of the three patients got well: yet I cannot doubt that, bating the hydatids, the disease was essentially of the same kind. It also occurred in a woman, whom I admitted into the hospital. She

was a kitchen-maid at the Thatched House Tavern in St. James's Street; and she had received a violent blow at the back part of the right hypochondrium. This was followed by pain there and by fever; and at length she began to have cough, dyspnoea, and expectoration. She brought up an abundance of frothy mucus of a bright yellow colour: not at all resembling the rusty sputa of pneumonia, but exactly of the tint which bile would give to it. At the same time large crepitation could be traced from the bottom to the top of the right lung. I fully expected that this woman would die: but by degrees the yellow expectoration ceased, all the auscultatory signs gradually disappeared, and she recovered perfectly.

It is plain that in such instances as this, there must be adhesion of the *lung* to the diaphragm also: but cases have occurred in which the matter burst into the cavity of the pleura, and presently destroyed the patient by suffocation.

The event of the third case is still *sub judice*. A gardener, 45 years old, was attacked, four weeks before he came under my care in the hospital, with severe pain in the right loin. Just at the edge of the short ribs, and not far from the vertebral column, on the right side, I found a large elastic swelling, very tender, and of a bluish red colour. As the patient's urine was most remarkably loaded with amorphous deposits, my first suspicions turned towards the kidney. It soon, however, became plain that, although the tumor was below the diaphragm, the parts above that muscle were involved in the disease. The right half of the thorax was dull to percussion; no vesicular breathing was audible there, but some scattered crepitation and bronchophony. Four days subsequently to his admission the patient began, during an effort of coughing, to discharge, almost in a stream, from his mouth, a considerable quantity of grey, pultaceous fluid, of the consistence of gruel, and horribly fetid. Altogether the amount of matter thus expectorated was estimated at two quarts. The pain then ceased; and the swelling was observed to be less. After three days more, it was deemed proper to puncture the tumor, and matter was let out having precisely the qualities of that which he had ejected through the mouth. The patient remained eleven weeks in the hospital, the expectoration becoming less unnatural, and the discharge from the abscess gradually diminishing. He then chose to depart. Some months afterwards he applied for re-admission, and again staid with us a week or two. His health had much improved during the interval: but the wound in his back was still open, and he still continued to expectorate somewhat: and yellow bile was frequently to be seen, both on the dressings

which covered the puncture, and in the vessel into which he spat. I think it probable that this man may eventually recover, at the expense, however, of a permanently damaged lung.

Rigors occurring during the progress of hepatitis should make us suspect that suppuration is taking place: if the pain is thenceforward mitigated, or exchanged for a sense of weight, and hectic fever sets in, we may be tolerably certain that pus has formed.

Of the several courses taken by an hepatic abscess, that towards the surface of the body is the most common; and it is the only one with which we are able to interfere. And the chief thing we have to look to, is not to interfere too soon. The adhesion of the inflamed organ to the wall of the abdomen is the indispensable condition, not of success only, but of safety, where the question arises of puncturing the tumor. Without such adhesion the pus will be transferred from the cyst to the cavity of the peritoneum; or if the abscess be not reached by the scalpel, that cavity will be laid open. Now it is not easy to ascertain whether there be adhesion or not. Certainly the operation ought not to be attempted until the parts above the abscess are very thin, and are verging to a point; and even then, unless there were some distinct purpose, besides that of saving a little time, some urgent distress or danger to relieve, I think such abscesses might be more prudently left to themselves. Dr. Gregory, of Edinburgh, used to mention a case in which, as fluctuation was palpable, and the tumor pointed, it was proposed to open it; but the patient died somewhat suddenly before the operation could be performed: and inspection of the dead body showed that no adhesion existed. Mr. Malcolmson has lately published, in the *Medico-Chirurgical Transactions*, two or three instances of a like kind. These are circumstances which teach us to be cautious about recommending the operation.

A case is recorded of the bursting of an hepatic abscess into the pericardium; another into the vena cava. Facts of this kind constitute mere medical curiosities, and have no practical bearing.

It is clear, both from the size of the organ and from its situation in the body, that an abscess in the liver can never be otherwise than gravely hazardous. Yet many recover from them. Much evidently depends upon the manner and direction in which the pus seeks a vent. The most desirable road for its exit is one which it sometimes takes, but which I have not yet mentioned. It occasionally flows out into the duodenum through the excretory ducts of the liver, when these happen to have been laid open by the suppurating process. Next to this we may hope for its discharge through the adhering pa-

rietes of the abdomen; next by a breaking of the abscess into the alimentary canal. The escape of the matter through the air-passages is fearfully perilous; and its entrance into the shut serous sacs, or into the great blood-vessels, almost necessarily fatal.

The causes of acute inflammation of the liver are principally those to which I have so many times had occasion to point: exposures to wet and cold, especially after the body has been submitted for a considerable period to the influence of a high atmospheric temperature. This opinion is the result of much experience collected by numerous observers of the disease in hot climates. But if you ask me for a reason why the liver gets thus ready to take on inflammation—why, when the inflammation is excited by cold, this organ in particular should be affected—I cannot give you one: any more than I can tell you why, under other circumstances, it is the throat, the intestines, or the lungs, upon which the inflammatory action fastens.

It was long supposed that injuries of the head had some peculiar and mysterious effect in producing suppuration of the liver. Hepatic abscesses, of small size, but several perhaps in number, are of frequent occurrence in the bodies of persons who have died of fracture of the skull. This particular fact has since been swallowed up in a more general one; viz. that collections of pus are common in various organs, and especially in the liver, as consequences of *phlebitis*, or of the entrance of pus into the veins from a suppurating wound.

Acute hepatitis requires vigorous treatment in the outset. Our object is, if possible, to prevent suppuration. Blood should therefore be freely taken from the system by venesection, and from the neighbourhood of the inflamed part by leeches. I will not weary you by going over the old ground that we have so often trodden already, nor repeat observations which have been many times made respecting the methods, and the requisite amount, of this great antiphlogistic remedy. Depletion of the portal vessels may also be indirectly obtained by purgatives; especially by such purgatives as produce copious and watery stools. The neutral salts are therefore proper in this disorder. It may be, as some suppose, that they operate beneficially, as counter-irritants, upon the duodenum; but their effect in draining the veins that feed the vena portæ, and thereby relieving the hepatic congestion, is more obvious and more intelligible. These saline medicines should be much diluted; and their action may be quickened, if that be necessary, by adding the infusion of senna.

After blood-letting has been duly performed, and the force of the inflammatory action has been broken, blisters may be applied to the right hypochondrium: and I

believe that repeated blistering is more serviceable than a single blister kept open by savine ointment.

Some difference of opinion prevails among medical men in regard to the employment of mercury in the *onset* of acute hepatitis. I cannot pretend to offer you the results of my own observation on this point, but I find that the best authorities, among those who have had to treat the disease in hot climates, are *against* its use at the *very first*, as being stimulating to the liver. I suspect that this is a piece of theory: but at all events, after the first violence of the inflammation has abated, that remedy is not to be omitted, either in the acute, or in the chronic form of the disorder, to be mentioned presently: only in the one case it should be so administered as to affect the system as speedily as possible; in the other it is to be introduced with a slowness which bears a proportion to the pace of the disease.

When suppuration has taken place, or is unavoidable, when the patient ceases to complain of pain, but has in its stead a feeling of weight in the hypochondrium, and becomes distinctly hectic, a corresponding change must be made in the treatment. Active depletion is no longer admissible; you must sustain the strength by a more nourishing diet, and prescribe some tonic remedies; the sulphate of quina, with sulphuric acid; or the nitro-muriatic acid, which enjoys a considerable repute, greater perhaps than it merits, for the relief of liver complaints.

Acute inflammation of the liver is apt to degenerate into *chronic*. Chronic inflammation may also arise under the circumstances that give birth to the acute form. Chronic hepatitis, again, is not unfrequently produced by the presence of specific disease in the liver, of what is called carcinoma; of scrofulous tubercles. Melanosis, and hydatids are both of them of common occurrence in the same part; and they may give rise to symptoms, or they may not: and when these morbid conditions do declare themselves by external signs, those external signs are very much the same as belong to chronic hepatitis. The precise diagnosis is exceedingly obscure; the symptoms point distinctly to the liver as the *seat* of the disorder; but as to its exact *nature*, we must often be content with probabilities alone.

The symptoms of chronic hepatitis—or of the chronic forms of disease to which I have alluded, when they show themselves by symptoms—are (I give you them in Cullen's words) "some fulness and some sense of weight in the right hypochondrium; some shooting pains felt at times in that region; some uneasiness or pain felt on pressure in that part; some discomfort from lying upon

the left side; perhaps some degree of jaundice; and sometimes a certain amount of fever combining itself with more or fewer of these symptoms." In short, they are just the symptoms of acute hepatitis occurring in a minor degree.

Chronic affections of the liver are sometimes attended with an *increase*, and sometimes with a *diminution*, of its size. When it is augmented in bulk, its place and enlargement may be ascertained by palpation and percussion; nay the magnified gland may sometimes be seen, extending beyond its proper situation in the hypochondrium, and passing far down into the abdomen. I have known the liver reach to the right groin: and when its left lobe is affected, it will sometimes stretch across towards the lower part of the left side of the belly. On the other hand the liver may shrink into a much smaller space than it naturally occupies. These small livers are usually hard. Interfering more with the portal circulation than many enlarged livers do, they are more frequently attended with dropsy of the peritoneum.

The "hobnail" liver, the *cirrrose* of modern French writers, is nodulated as well as hard. The irregularity of its surface may be so great as to be perceptible to the touch. I fully described this condition of the liver when I was upon the subject of passive ascites, of which it is the most common cause.

I mentioned also, some time ago, the "fatty" liver, so frequently found associated with pulmonary consumption. The liver in this state is soft, enlarged, smooth on its surface, and of a buff or tawney colour throughout. Mr. Bowman has lately shown that these changes are owing simply to the unwonted abundance of certain small granules of fat, of which, in the healthy organ, each lobule contains a few only. If in a phthisical patient we find the liver palpably enlarged, we may guess that it is encumbered with this interstitial fat: but there are no symptoms peculiar to the fatty liver. As to its cure, we are quite helpless: and the same may be said of the hobnail liver, as well as of all those forms of disease in which the organ is loaded with specific deposits.

Dark masses of extravasated blood are sometimes found interspersed through this gland, and then, by an absurd perversion of language, the patient is said to have had "apoplexy" of the liver.

The same causes which produce acute hepatitis, acting in a less intense degree, will excite chronic inflammation of the same textures. Intemperance also, and particularly the habitual and excessive use of alcoholic liquors, certainly tends to generate hepatic inflammation, especially in its more chronic form. We see this even here, and it is still

more strikingly perceptible in warm climates, as you may learn by reading the works of those persons who have had experience of the diseases of India. Dr. William Ferguson, for example, who was for some time chief of the medical staff of the windward and leeward islands in the West Indies, observed that there was a regular increase and aggravation of these chronic affections of the liver among the troops after they received their monthly pay, when they drank great quantities of ardent spirits; arrack in the East Indies, and rum in the West.

There has long been supposed to be what is called a *gin-drinking* liver, in which a section of that gland presents an appearance very closely resembling the section of a nutmeg; and a good deal of useless speculation has been employed as to the nature of the change which has taken place in such cases. Mr. Kiernan has clearly shown that the nutmeg aspect of the liver is produced by mere congestion of blood. Congestion of the liver is, indeed, very likely to arise under the daily stimulus of distilled spirits, but it arises under various other circumstances besides; and therefore it is no safe test of the intemperate habits of the party. And of this we had sufficient evidence before Mr. Kiernan's observations were published. Again and again have I met with the nutmeggy liver, strongly marked, when there was reason to believe that the possessor of it had never transgressed the strictest rules of temperance in drinking: in young persons, for example, of both sexes, who certainly never had been dram-drinkers. Disease of the heart is a very obvious, and a very common cause of hepatic congestion.

You are aware that the congestion occurs under two forms, according as the branches of the hepatic vein, or of the vena portæ, are gorged. If both these sets of vessels are full, the liver is universally red. If the hepatic vein alone be the seat of the congestion, then in the centre of each lobule we see a red speck, surrounded by yellowish matter; the specks are isolated, the yellow colour is arranged in a sort of net-work. Whereas, if the portal system be greatly engorged, the red streaks will be continuous, and the yellow portions hemmed in by them, and isolated. I show you these distinctions in some specimens prepared by Mr. Kiernan himself.

I should have stated, when speaking of the signs of chronic hepatitis, what is singularly true of chronic liver affections in general, that they are apt to be attended with much languor and lassitude, and a remarkable depression of spirits; and with that sort of dread, and apprehension of impending evil, which I mentioned as being a striking feature of hypochondriasis: the very derivation of which term marks its frequent

connexion with hepatic disorder. There is sallowness of the complexion also; and sometimes emaciation.

The same remedies are adapted to the chronic as are proper for the acute inflammation of the liver: the comparative mode of their exhibition however differs somewhat.

Blood-letting is not often necessary or advisable, except when more violent aggravations than usual of the inflammatory symptoms supervene. Topical bleeding, and blistering, are more expedient.

But the two main remedies to be tried in this complaint are mercury, and the saline purgatives, given in small doses, and repeated for a long time together. Five grains of blue-pill every night, or every night and morning; and as much of the sulphate of magnesia as will produce one or two watery stools every day, for weeks, perhaps, together. Patients are not so well content to bear this discipline when it is administered in boxes and phials, *as physic*; but they have more faith in the natural mineral waters: so that a residence at Cheltenham, or some such place, is exceedingly proper to be recommended in these cases; where the daily use of the waters may keep up a continual drain on the system of the vena portæ; and where the relaxation from business, the amusements that are constantly going on, the change of scene and of society, may contribute to dissipate the hypochondriacal feelings which are so apt to render the subjects of chronic hepatic disease supremely wretched.

Moderate exercise, in the open air, on horseback and on foot, should be encouraged. There is no doubt that hepatic as well as gastric derangements are fostered by sedentary habits. Tepid bathing is another expedient from which benefit may be hoped. In many instances it will be proper to make trial of Scott's nitro-muriatic bath.

*Iodine* has been thought of much use in certain kinds of hepatic disease; in those kinds especially which are connected with enlargement of the viscus. The iodide of potassium; or a mixture of the iodide and of iodine; or some of the combinations of iodine and mercury; may be given in such cases: or the *unguentum iodini compositum*, or the *unguentum hydrargyri iodidi*, of the Pharmacopœia, may be rubbed night and morning upon the hypochondrium. I have not seen much benefit from these forms of medicine myself, in such cases; but they are said, by persons of experience and credit, to have been successful in their hands.

*Taraxacum* is also a drug which has been much employed in liver complaints since Dr. Pemberton's book on the diseases of the abdomen was published; but it is very doubtful, in my mind, whether it ever does much good. The Germans are very fond of

giving the *muriate of ammonia* in small and frequent doses. They have the same belief in the virtues of this salt, in various disorders, as the English practitioners have in those of mercury; and what is curious, they attribute to it some specific agency upon the functions of the *liver*.

In the account which I have now given of the principal diseased conditions of the liver, I have not included, nor dwelt upon, all the changes of structure and appearance to which that organ is liable. There are various conditions which disclose themselves by no intelligible symptoms during life, of which the nature has not yet been determined, and of which the cure still remains to be discovered. At this advanced period of the course, and with no time to spare, I do not think it necessary or right to trouble you with the unprofitable discussion of matters that are not strictly practical.

I have mentioned *jaundice* as an occasional symptom both of acute and of chronic inflammation of the liver. But jaundice is spoken of, in general, as constituting, itself, a distinct form of disease. If we consider it in that light, its diagnosis is most easy. We have only to look upon our patient to know what is the matter with him. But jaundice depends upon various and very different morbid conditions; and looking to those conditions as the true objects of diagnosis, we find that the real nature of a given case of jaundice is often involved in very great obscurity.

Let us first consider the constituent features of jaundice, whether it be regarded as a *disease* or as a *sign of disease*. They are, yellowness of the skin and of the eyes; whitish *fæces*; urine having the colour of saffron, and communicating a bright yellow tinge to white linen.

The characteristic yellow hue is owing, no doubt, to the presence of bile, or at any rate of the colouring matter of the bile, in the circulating blood. And the deep tint of the urine is evidently derived from the same source. On the other hand, the paleness of the *fæces* is to be ascribed to the want of bile, which always exists in healthy and natural excrement. This last symptom is not, however, a constant one; there may be jaundice while bile appears in the stools. I shall explain how this is supposed to happen presently.

It has been made a question how the bile, or its colouring matter, comes to be visibly present in the blood, or rather in many of the tissues supplied by the blood, and in several of the other fluids of the body. The general opinion, and probably the true one, is, that the bile, after being secreted in the liver, is reabsorbed, and carried into the circulation, and so conveyed to the surface,

and to the parts in which the change of colour is observed. This explanation is consistent with all the phenomena which we notice in the disorder.

But another theory has been broached on this subject; first, I believe, in this country, by Darwin. It has been more recently revived by M. Chevreul, who is followed by Mr. Mayo. These pathologists are of opinion that the bile is formed, not by the liver, but in the blood: that the office of the liver is to strain off or withdraw the bile from the circulation, constantly, as fast as it is formed; just as the perpetual elimination of urea from the blood appears to be one great purpose of the kidneys. They hold, therefore, that jaundice manifests itself whenever the due separation of the bile from the blood is suspended or imperfect. Failing of its natural vent, this peculiar substance accumulates in the blood, seeks other outlets, is deposited in various places, and, in fact, partly escapes through unaccustomed channels. They speak of jaundice as a symptom of *suppression* of bile, while others consider it as a sign of *retention*; using these words, suppression and retention, in the sense in which they are applied to the secretion of urine. They maintain that the proper function of the liver, the abstraction of bile from the blood, may be arrested by alterations of the substance and structure of that gland; or by the obliteration or obstruction of the gall-bladder or ducts, impeding or forbidding the removal of the bile already formed; or by some obscure influence of the nervous system upon these organs. They introduce the last kind of cause with the view of explaining those cases, which certainly occur, in which jaundice is the result of severe bodily pain or strong mental emotion. Nay, on their supposition, we might even suppose that the yellowness is sometimes due to a spontaneous and unwonted *abundance* of the elements of bile in the blood: in which case we need not wonder that jaundice should go along with perfect integrity of the biliary apparatus.

The advocates of the first mentioned supposition are aware of the difficulties opposed to its reception, by the occasional absence, even in cases of well-marked jaundice, of all disease or apparent obstruction to the excretion of the bile. They shew that in very many cases there is some obvious mechanical obstacle to the efflux of the secreted fluid: and in those instances in which none can be discovered after death, they conceive either that the ducts of the liver had been temporarily plugged up by inspissated bile, or a sort of biliary sand—or that they were closed, for a time, by spasm—or by some morbid condition of the duodenum.

Now of these two hypotheses, that which ascribes the yellowness to the reabsorption

of the secreted bile, is, to my mind, the most probable and the simplest: and I cannot see that it is attended with *more* difficulty than the other. But you may choose for yourselves between them: and I pass from this digression to a somewhat closer examination of the principal circumstances noticeable in the complaint. Its technical appellation, I should observe, is *icterus*, which is a Greek name for a bird with a yellow plumage, the galbula, or golden thrush; the sight whereof, by a jaundiced person, was death (Pliny tells us) to the bird, and recovery to the patient. Various other terms have been applied to the disorder, most of them having reference, like jaundice itself (from the French *jaune*), to the unnatural colour. *Morbus arquatus*, from its exhibiting some of the bright hues of the rainbow; *aurigo*, from its resembling gold; and we hear the common people say, now-a-days, such a one is as yellow as a guinea. The Latins spoke of it also under the title of *morbus regius*: why they so called it we learn from the following curious passage in Celsus, giving an account of the pleasant regimen, fit for Royalty itself, to be adopted by those who labour under the malady. “Per omne vero tempus utendum est exercitatione, frictione: si hiems est, balneo; si æstas, frigidis natationibus; lecto etiam et conclavi cultiore, lusu, joco, ludis, lasciviâ, per quæ mens exilaretur: ob quæ regius morbus dictus videtur.”

The whiteness of the stools I have mentioned as being a very common but not a constant appearance. It clearly depends upon the absence of bile. But sometimes there is bile in the discharged fæces, and at the same time the yellow colour of the skin and eyes. This probably depends upon the circumstance that some branches of the hepatic ducts are obstructed while the others are free; and thus the bile that is secreted is, in part, reabsorbed into the blood, and in part carried off into the intestines. In a former lecture I stated that one of the uses of the bile appeared to be that of stimulating the bowels to action: it is the natural purgative. Accordingly, in most cases of jaundice, the bowels are costive. But neither is this uniform. In some of the worst cases, wherein the jaundice depends upon hepatic disease, which is connected with disease also of the mucous coat of the intestines, there is constant diarrhoea.

In some instances the yellowness of the skin is at first attended with itching, which is occasionally so intolerable as to require the employment of opiates to allay it. In most cases there is no itching at all. The bile never fails to appear in the urine, which is in itself dark, and when collected in considerable quantity in a deep vessel, even *black*; and which tinges any white substance that is dipped into it of a bright yellow.

The urine which thus sometimes seems black, may be proved to derive that appearance merely from concentration of the yellowness, by pouring a little of it into a shallow white dish, or by diluting it with water; when the brilliant yellow tint will become manifest. Bilious sweat sometimes occurs, staining the patient's linen yellow. The saliva, in some jaundiced persons, has the same yellow tinge, and a distinctly bitter taste. It has been said that the milk of women who are nursing is made yellow in this disorder. Dr. Heberden, however, states that he never witnessed this; and he had known a woman with a very deep jaundice upon her, suckle her infant for six weeks together with no apparent bad effects upon its health. One man assured him that his tears were yellow. You are aware of the vulgar notion, that to a jaundiced eye all things appear yellow. Lucretius seems to have been the first to mention this:—“*Lu-rida præterea fiunt quæcunque tuenter Arquati.*” Heberden was disposed to regard this as being a mere poetical fiction. But certainly it is sometimes, though very rarely indeed, the fact. Two women, whom he considered however to be of little credit, told Heberden that objects appeared yellow to them. I have been assured of the same thing by a medical man who experienced it in his own person. If I do not mistake, Dr. Mason Good saw all things yellow when he was jaundiced. Dr. Elliotson has had some very interesting cases of this phenomenon. One of his icteric patients declared that objects seemed yellow when looked at with one eye, but not with the other; and in the eye that perceived the yellow tint he observed two large red vessels running towards the cornea. And in one or two instances, which he met with afterwards, of yellow vision with both eyes in jaundiced patients, he found inflammation, or distended blood-vessels in both eyes. This very morning I saw in the hospital a patient of Dr. Wilsoff, a middle-aged woman, affected with jaundice. She affirms that all objects seem yellow to her vision. In both eyes there are several varicose and singularly tortuous vessels, proceeding across the sclerotica towards the cornea, and some of them reaching its margin. It seems probable therefore that the ophthalmic vessels, in their natural state, do not permit the colouring matter of the bile to pass through them; but that when they become enlarged by disease, so as to admit the colouring particles of the blood, they may also give a passage to the yellow colouring matter, which tinges the humours of the eye: and in that case the objects seen through the yellow fluids would appear like those viewed through a piece of yellow stained glass. This is a point which is worth your attention in future.

The shades of yellowness are different in

different patients. Those who are pale and fair present a bright lemon colour. But in those who are florid, or whose cheeks and skin are flushed with fever, the tint will more resemble that of the Seville orange. Again, if the patient be naturally swarthy, or if his visage is livid or dusky through imperfect arterialization of his blood, the superaddition of jaundice will give him a greenish hue. These differences result from natural or acquired differences of complexion, antecedent to the icterus. But sometimes the bile that is reabsorbed is vitiated and dark; and we may have, as Dr. Baillie has pointed out, cases of green or black jaundice from that cause. You will remark that from whichever cause the green or dark colour arises, whether from a mingling of the yellowness of the bile with the blueness of lividity, or from the circulation of green-coloured bile, such cases are especially unpromising cases.

Icterus depends, as I have said, upon various and different internal causes: and frequently we cannot determine at all, until death affords us the means of inspecting the parts concerned in its production, what the precise exciting cause may be; even when it is simply mechanical. Any kind of pressure made upon the excretory ducts of the liver will produce it: and such pressure may be exercised by tumors seated in the liver itself; or by a scirrhus pylorus; or by specific disease situated in the head of the pancreas, of which I have seen several examples; or by a diseased condition of the duodenum: and these possible causes of a detention of the bile in its receptacle should always be borne in mind when we are investigating an obscure case of jaundice.

The impediment, in the cases just supposed, is external to the ducts; but they may be obstructed within, plugged up by inspissated bile, or by a biliary calculus. This forms one of Cullen's species of icterus—the *icterus calculosus*. The concretion is most commonly situated, I believe, in the ductus choledochus; sometimes, however, in the cystic, and sometimes in the hepatic duct. The pain that attends the passage of a gall-stone through these ducts is often dreadful. Perhaps there is no pain to which the body is subject that is more severe. You will not wonder at this, when you consider that through a tube, of which the natural size scarcely exceeds that of a goose-quill, there sometimes passes a stone as big as a walnut. The common duct has been found so dilated as readily to admit one's finger. Cullen's definition of this species is "*Icterus, cum dolore in regione epigastrica, acuto, post pastum aucto, et cum dejectione concretionum biliosarum.*" Now the last of these circumstances, the voiding of biliary calculi by stool, may happen over and over again, without its being noticed, and it does not

help us at all to judge of the nature of the complaint at its commencement, while the gall-stone is still in the ducts. With the pain, which is not constant, but comes and goes, there is much nausea and vomiting; and sometimes hiccup; and the matters vomited are usually very sour. The patient is flatulent, and dyspeptic; languid, and gloomy. At length the concretion passes into the intestines; the pain suddenly ceases, and all is soon well again. Attacks of this kind, having happened once, are very apt to be repeated.

Now this pain you might readily mistake for the pain of inflammation, were it not marked by these two circumstances—the absence of tenderness, and the absence of fever. Pressure, instead of augmenting, usually mitigates it. The patient keeps his hand firmly applied to his epigastrium; or rests, perhaps, the weight of his body upon some hard substance placed beneath his stomach. I speak now of the beginning of the attack, before there has been much retching; for a degree of tenderness of the abdominal muscles is often produced by repeated straining and vomiting. The pulse is unaffected, or I should rather say it is not accelerated, during the pain: occasionally it is even slower than natural, and the skin cold. Though there be no inflammation, rigors may occur; just as they sometimes happen when a solid substance—a bougie to wit—is passed through, and distending the *urethra*.

Nevertheless, inflammation does sometimes arise, and then the pulse becomes frequent, and the skin hot, and thirst and headache are complained of, and the epigastrium is tender; and if blood be drawn it exhibits the buffy coat. Sometimes the gall-stone makes its way, by ulceration, through the contiguous structures, and is so discharged outwardly, or into the bowels. In such cases there must have been inflammation.

As jaundice often occurs without any pain, so a gall-stone may enter and pass through the ducts, and produce pain, when there is no jaundice. The cystic duct alone may be blocked up, and that portion only of the bile be prevented from escaping which is accumulated in the gall-bladder. It is probable that re-absorption of the contents of that cistern is not very active. Or a calculus of an angular shape may stick in the common duct, and thus impede, without entirely stopping, the egress of the bile. Dr. Heberden thought that gastrodynia was not unfrequently owing to biliary concretions: founding his opinion upon the fact that many persons suffer, for months or years, under occasional attacks of epigastric pain, which is at last associated with jaundice. But after all, this might happen from progressive disease in the stomach itself;

and it is a pity that Dr. Heberden's views were not fortified by dissections.

When once a large calculus has forced its way through the natural channels of the bile, they remain permanently dilated; and smaller stones may be afterwards voided without pain or other notice of their passage. There are persons who get rid of scores of them in this way, during the course of their lives.

Sometimes a large concretion, after its extrication from the biliary passages, lodges in the more capacious intestines, and gives rise to serious obstruction there. I mentioned, recently, one case of this kind which had fallen under my own notice. But in general the concretions are expelled with the stools: and they should always be looked for. The patient is much gratified by seeing that his enemy has been expelled; and also by the proof he thus obtains of the sagacity and judgment of his physician. The *fæces* should be mixed with water, upon the surface of which any gall-stones, since they are specifically lighter than that fluid, will float. I never but once succeeded in thus catching a concretion in the evacuations of a patient, whose symptoms had led me to search for it.

We often find gall-stones, even in vast numbers, in the gall-bladders of persons who during their life time had never been known to suffer pain about the liver, or to have jaundice, or to exhibit any token of the presence of such concretions. We infer from this that, while they remain in the reservoir of the bile, they are harmless; and that the suffering and the hazard they occasion are mechanical consequences of their transit through the gall-ducts. I have heard of an instance in which upwards of 1300 gall-stones were taken from a human gall bladder after death.

These gall-stones are not, as you might suppose, mere lumps of inspissated bile. There are, I believe, concretions of that kind, but they are very rarely met with in the human subject. The ordinary calculi consist, in a great measure, of a peculiar substance, *cholesterine*, which exists in a state of solution in healthy bile, but which, in some morbid conditions of that fluid, being released from its solvent, assumes its proper crystalline form. Very little is known respecting the circumstances under which the change takes place. Cholesterine, Dr. Prout tells us, is the product of some modification of the oleaginous principle. Biliary concretions seldom form in children. They are much more common in women than in men. They occur most frequently in persons who are corpulent, and lead sedentary lives, and live well, and sleep much, and neglect their bowels: all which things foster or denote a torpid and congested state of the hepatic system. Cattle

are said to be subject to biliary calculi when shut up in stalls during the winter, and to lose the complaint when they are again turned out into the pastures in the spring. Hence the absurd notion, countenanced even by Van Swieten, that *grass* is a good remedy for jaundice.

Another variety of jaundice, also noticed by Cullen, is supposed to depend upon mere spasm of the gall-ducts. "*Icterus spasmodicus*, sine dolore, post morbos spasmodicos, et pathemata mentis."

Now the existence of this cause is hypothetical. The gall-ducts, though not distinctly muscular, possess a vital power of contraction. I am not aware that the disease has ever been clearly traced to a connection with "*morbi spasmodici*." It is an alleged cause which we can neither prove nor disprove. Certainly the "*pathemata mentis*" play their alleged part: fits of anger, and of fear, and of alarm, have been presently followed by jaundice: and it has also been produced by great bodily suffering, by a severe surgical operation, or, perhaps, by the dread which attended it. Mr. North witnessed a case in which an unmarried female, on its being accidentally disclosed that she had borne children, became in a very short time yellow. A young medical friend of mine had a severe attack of intense jaundice, which could be traced to nothing else than his great and needless anxiety about an approaching examination before the Censor's Board at the College of Physicians. There are scores of instances on record to the same effect: and *this* is observable of such cases, that they are often fatal, with head symptoms: convulsions, delirium, or coma, supervening upon the jaundice. But with respect to the immediate cause of the icteric symptoms, they may, I say, depend upon a spasmodic constriction of the gall-ducts. Mr. Mayo has suggested another cause, viz. the sudden formation of bile in unusually large quantity in the blood, by some influence propagated through the nerves.

Jaundice sometimes supervenes upon violent and long-continued vomiting; in which case the extremity of the gall-ducts is supposed to have been compressed by the coats of the duodenum.

Jaundice may also occur, as I stated before, as a symptom of acute or chronic inflammation of the liver; and then its treatment will merge in that of the primitive disease that has given rise to it.

Icterus occasionally comes on during pregnancy; and disappears after child-birth. The pressure of the gravid uterus may thrust other organs, a loaded colon for example, against the liver, and so impede the passage of the bile. The little exercise that pregnant women are apt to take, and the costive-

ness that frequently attends their condition, may have some influence in causing the *icterus gravidarum*.

All systematic writers follow Cullen in making jaundice a common disorder among newly-born children. The *icterus neonatorum* comes on, they say, a few days after birth; is not attended with any suffering, or obvious disturbance of the bodily functions; and soon disappears. Now there seems reason to believe that this is not icterus at all; and has no relation to the biliary organs. The surface of the infant, at its birth, is frequently of a deep-red, from hyperemia or congestion of blood; presenting a condition which falls little short of a mild but universal bruise. By degrees the redness fades, as bruises fade, through shades of yellow into the genuine flesh-colour. Such, I am assured by those who are more conversant with these matters than myself, is the pathology of the *icterus infantum*. Of course true jaundice may, as well as most other complaints, befall the earliest period of life; but I conceive that it seldom does.

The prognosis in jaundice is generally favourable; except when it depends upon structural disease of the liver, or supervenes suddenly upon some great mental or bodily shock. In both these cases the prognosis is bad, or doubtful. It is better, in that variety connected with hepatic disease, if the disease proceeds from some known cause, by which a low degree of inflammation has been produced; and the cause is such as can be avoided for the future. Just, indeed, as in chronic hepatitis, of which the icterus is simply an occasional symptom. The prognosis is worst of all in old persons, when the constitution is impaired, and there is no obvious cause for the disease; and particularly when the colour of the skin is greenish, or approaching to black.

## ON THE PULSE.

By the late JAMES HOPE, M.D. F.R.S.

Physician to St. George's Hospital.

[Concluded from p. 316]

### II. A comparison between the pulses of organic disease of the heart and those produced by ordinary causes.

I HAVE made experimental observations on this subject during the last three years, by taking written notes of the speed, quality, and circumstances of the pulse in about 8,000 cases, constituting nearly the whole of my out-patients at St. George's Hospital during the period alluded to.

Let us previously glance at the more simple qualities of the pulse, to obviate ambiguity as to terms.

*Magnus*—large, full.

*Parvus*—small.

*Validus*—strong (therefore “incompressible”).

*Debilis*—weak (therefore “compressible”).

*Durus*—hard (i.e. strong and abrupt).

*Mollis*—soft.

*Tardus*—prolonged (i.e. the distended state of the artery dwells long).

*Celer*—jerking, i.e. each beat is short and quick, as if the blood were “jerked” or shot under the finger; the artery in the intervals feeling unusually empty.

*Rarus*—infrequent or slow.

*Frequens*—frequent or quick.

*Intermittens*—intermittent, i.e. one, two, or even three beats are dropped, and the ensuing beat occurs at the regular interval. Sometimes the intermediate beats, instead of being wholly dropped, are slightly perceptible, rendering the pulse “unequal” as well as intermittent.

*Non-intermittens*—unintermittent.

Irregular, i.e. the beats recur at irregular intervals.

Regular, *vice versa*.

*Inæqualis*—unequal, i.e. where some beats are stronger than others. This pulse is generally irregular and intermittent also.

*Æqualis*—equal.

These simple qualities of the pulse may exist variously combined; and it is, indeed, principally in their combinations that we see them in nature.

I proceed to notice the states, whether simple or compound, which are of most common occurrence; and I shall first assign the ordinary causes of each variety, and then contrast each with the same pulse as produced by organic disease of the heart.

1. *The strong pulse* (therefore “incompressible”) proceeds from constitutional vigour or tone, imparting powerful contractility of the heart and arteries. It may also proceed from the heart being naturally strong-walled; for some hearts have thicker and others thinner walls than the average, yet both short of disease (Laennec).

*Cardiac causes*.—The same pulse may be produced, even in the feeble and atonic, by simple hypertrophy of the left ventricle (i.e. thickening of the walls without alteration of the cavity):

the strength of the pulse being referable to the increased muscular power of the ventricle. In great degrees of hypertrophy the pulse is also somewhat "prolonged," because a thickened ventricle contracts slowly.

2. *The strong and large pulse.*—The strength proceeds from the same circumstances as in No. 1. The largeness may be attributable to the large size of the individual, or to plethora distending the vessels, or to the naturally large calibre of the particular arteries examined.

*Cardiac cause.*—The same pulse, but often in a much higher degree and more "prolonged," is occasioned by hypertrophy, with dilatation of the left ventricle (*i. e.* thickening of the walls with enlargement of the cavity). The strength is owing to the increased muscular power; the largeness, to the increased capacity of the ventricle, whence an inordinate quantity of blood is forced into the arteries; the "prolongation" is owing at once to this preternatural repletion of the arteries, and to the longer time occupied by the heart, thus enlarged, in completing its contraction.

REMARKS.—The strength, largeness, and tense prolongation of the pulse of hypertrophy with dilatation, are sometimes so remarkable, that, in the absence of inflammatory and certain comatose affections, which alone can create a sound even approximating to this, the practitioner may generally make a successful guess at the disease from the single sign of the pulse. It must be understood that I do not attach the slightest value to a guess.

The pulses of hypertrophy, and hypertrophy with dilatation, present occasional exceptions; for depressed state of the nervous system, and debilitating causes in general, may neutralize the contractile energy of the heart: also, during great palpitation and dyspnoea, when the ventricle is gorged and incapable of adequately expelling its contents, the pulse may become small and weak. These exceptions, however, being generally referable to obvious causes, confirm rather than invalidate the general rule.

3. *The large and soft pulse,* and therefore "compressible." The largeness proceeds from the same causes as in No. 2; the softness from deficient constitutional tone, as in the aged, or

the enfeebled by disease or any other causes.

*Cardiac cause.*—The same pulse is occasioned by dilatation with hypertrophy of the left ventricle, *i. e.* enlargement of the cavity predominating over hypertrophy of the walls, so as to diminish their contractile power: hence the pulse is soft; while, from the preternatural quantity of blood expelled by the enlarged cavity, it is large. It is likewise somewhat prolonged. This pulse is liable to the same exceptions as the cardiac pulse No. 2.

4. *The hard pulse,* *i. e.* strong and abrupt.—It is generally, though not always, frequent. This is the characteristic pulse of inflammation and of ardent fever (the synocha of Cullen). It is more marked in inflammation of serous, cellular, and fibrous, than of other tissues. Even "active congestion" may occasion a moderate degree of the hard pulse. It may be absent in the atonic inflammation of feeble constitutions; or it may be replaced by a minor degree of hardness denominated "sharpness," viz. the pulse, though comparatively weak and small, is abrupt—a variety not easily distinguished, except by its cause, from the "jerking" pulse of anæmia. In fact, when an anæmic subject is attacked with inflammation, the "jerking" is converted into the "sharp" pulse.

*Cardiac causes of the hard pulse.*—If the strong pulse of simple hypertrophy, or the strong, large, and prolonged pulse of hypertrophy with dilatation, be moderately accelerated by any excitement, whether healthy or morbid, it acquires an abruptness in addition to its strength, which renders it preeminently hard: so that it is not exceeded, and often not rivalled, by the hardest pulse of serous or fibrous inflammation. It is frequently mistaken for an inflammatory pulse.

5. *The bounding pulse.*—This is a large and sudden swell or bound, without the strength and incompressibility of the hard pulse. It is always frequent. We see this variety in healthy persons when excited by violent exercise; in palpitation from nervous or mental excitement; in paroxysms of febrile excitement, as, for instance, during the influence of a stimulant diaphoretic; and it is common in acute rheumatism. It is often confounded

with the hard pulse, and injudiciously taken as an indication for bleeding—a dangerous mistake; for, as the bounding pulse is one of excitement, its subsidence is apt to be followed by exhaustion; and if this be unduly increased by unseasonable bleeding, it may issue in irrecoverable sinking.

*Cardiac cause.*—If the large soft pulse of simple dilatation be accelerated, it presents the bounding character in perfection.

6. *The "wiry" or "cord-like" pulse: i. e.* small, hard, and tense, like wire or cord, and always quick. This is considered to be the characteristic pulse of enteritis. The smallness is ascribed to the sedative impression produced on the nervous system by severe inflammation of the stomach and bowels. When, however, this sedative impression has attained a certain degree, the wiry hardness ceases, and leaves the pulse exceedingly small, weak, and quick; sometimes barely perceptible. Appropriate bleeding renders the wiry pulse larger, softer, and slower.

*Cardiac cause.*—Hypertrophy, with contraction of the left ventricle, occasions a small, strong, tense pulse, which becomes hard on acceleration. The smallness is owing to a deficient quantity of blood being impelled into the aorta; and the strong tension, to the increased force with which it is impelled by the thickened ventricle.

An exception presents itself when the capacity of the ventricle is diminished to a great degree; for, as the quantity of blood then expelled is insufficient to distend the arterial system, the pulse is weak as well as small. It is partly from having overlooked this exception, that some have denied the general fact that hypertrophy produces a strong pulse.

7. *The prolonged pulse\*, i. e.* the beat, being slowly performed, dwells long under the finger. The frequency of the beats is generally diminished, though, occasionally, it is increased;

\* I have employed the epithet "prolonged," because there is no English word at present in use which unequivocally represents the Latin word "tardus." The usual translation of it is, *slow*; but the word *slow* is commonly understood to imply *not frequent, i. e. rarus*, whereas the word *tardus* has no reference to frequency, but imparts *slowness of the individual beats*, which the term "prolonged" expresses without ambiguity. I offer this apology for presuming to introduce a new epithet.

but if the rapidity become great, the prolonged character ceases to be appreciable.

The prolonged pulse is seen in various states of cerebral stupor and coma, by which the contractile activity of the heart and arteries is diminished. The full slow pulse, common in apoplexy, and the oppressed pulse of cerebral concussion and cranial depression, and of inflammation of the brain during its transition into the comatose stage, present the most familiar instances of the prolonged pulse. I have also seen it during the apnoea of universal vesicular bronchitis, when the brain was oppressed by the circulation of insufficiently oxygenized blood.

*Cardiac cause.*—The prolonged pulse is occasioned by simple hypertrophy, and pre-eminently by hypertrophy with dilatation, being referable to the longer time occupied by the enlarged and thickened ventricle in the completion of its systole.

8. *The jerking pulse, i. e.* a remarkable brief, abrupt beat, with little or no strength, and with a feeling of emptiness of the artery in the intervals between the beats. This is the pulse of anæmia, when, from the blood being deficient in quantity, and too aqueous in quality, the arteries are not full and tense. We see it follow excessive losses of blood, whether sudden or chronic; also in chlorosis, and after chronic diarrhoea, leucorrhœa, starvation, protracted fever, or any exhausting diseases or circumstances which drain the system, impoverish the blood, and impart a pallid hue to the lips and complexion. The anæmic pulse is almost always quick, and the patient subject to palpitation on exertion. It is a pulse highly important to be understood, as it is very apt to be confounded with the bounding, the sharp, and even the hard pulse.

*Cardiac cause.*—The jerking pulse is occasioned by regurgitation through the aortic valves into the left ventricle, or through an aneurismal opening out of the aorta into either ventricle, or into the pulmonary artery—all which lesions prevent fulness and tension of the arterial system. The pulse, therefore, is still that of "unfilled arteries," and it illustrates the same state as resulting from anæmia, by a striking and beautiful mechanical analogy. When the regurgitation is very free,

the jerk may exceed that of the most decidedly hæmorrhagic or anæmic pulse, of which I recently witnessed a remarkable instance in a case of free regurgitation from the aorta, through an aneurism, into the right ventricle (John Mitchell, Westminster Hospital, under Dr. Roe): it is felt as if a hard ball were shot violently under the finger through an empty artery.

I have already stated that the jerking pulse of aortic regurgitation has been hitherto unnoticed by authors: so striking, however, is the phenomenon, that I have been in the habit of "guessing" from this sign alone, in the absence of anæmia, that, on placing a stethoscope over the aortic orifice, a murmur from regurgitation would be heard with the second sound: and rarely has this sign proved fallacious. Another consideration, however, contributes to the success of such a guess; namely, that the pulse of regurgitation may be as slow as natural, whereas that of anæmia is almost invariably and necessarily frequent, ranging from 90 to 130.

9. *The small and weak pulse.*—This is usually connected with delicacy of frame and constitution; and often with a thin-walled heart. It may also be occasioned temporarily by extreme plethora and obesity, under which circumstances it generally rises on bleeding.

*Cardiac cause.*—The small, weak pulse occurs in the later stages of dilatation with attenuation of the walls of the left ventricle\*: also in softening of the heart, and in hypertrophy with extreme contraction of the left ventricle†. I have occasionally seen it produced, though rarely in a considerable degree, by contraction of the aortic valves or orifice.

10. *The small, weak, and frequent pulse.*—This is from morbid debility howsoever occasioned; as, for instance, by the advanced stages of fever, of inflammation, of chronic diseases, &c.

*Cardiac cause.*—The small, weak, and frequent pulse occurs in the palpitations of dilatation, of softening, and of hypertrophy with great contraction.

11. *The fluttering or vermicular pulse:* i. e. so small, weak, and fre-

quent, as to be a mere flutter, or to feel like the movement of a worm. It proceeds from exhaustion and sinking; sometimes also, from nervous agitation, in which case it is only temporary.

*Cardiac causes* will be enumerated under the next head.

12. *The intermittent, irregular, unequal, small, and weak pulse.*—Several, or all of these qualities, may be occasioned by dyspepsia with nervousness, especially in gouty and bilious subjects: they may even result from nervous disturbance alone. I have repeatedly seen the whole exist simultaneously and in the highest degree, from these causes. The attacks are only occasional and temporary.

*Cardiac causes.*—The whole of the above qualities of the pulse almost always exist in a marked degree, and permanently, in great contraction of the mitral valve, and in free regurgitation through it; being attributable, I presume, to the irregular supply of blood to the left ventricle. I have also seen them once or twice in extreme contraction of the aortic valves, leaving an aperture not larger than a goose-quill. In moderate contraction, the regularity of the pulse is rarely affected, though its volume and strength may be somewhat diminished. I have also repeatedly seen all the above irregularities in a marked degree in chronic softening with dilatation. Moderate intermittence, irregularity, and inequality, are common in the last stage of mere dilatation, and I have occasionally seen them in the last stage of hypertrophy. In both cases they are probably referable to a failure of nervous power. Again, all the above qualities may exist in a high degree in pericarditis with copious effusion compressing the heart, in carditis, and in endo-carditis, with coagulation of blood choking its cavities (M. Bouillaud); also in cases of the sudden formation of polypus in any disease of the heart\*. In any of the instances cited, the pulse may become "*fluttering or vermicular*," during agitation or palpitation.

Intermittence from *ordinary* causes, never presents, according to my observation, the following varieties, which I have frequently met with in disease of the valves of the heart, and which are distinctly described by Galen and others

\* In the early stage it is sometimes large, though weak.

† This was not noticed by Bertin and Bouillaud, though they distinctly say that concentric hypertrophy, if great, constitutes an obstacle to the circulation. I find, however, that Bouillaud, in his subsequent work in 1835, properly describes the pulse as small and weak.—*Traité*, tom. ii. 533.

\* See Treatise on Diseases of the Heart, by the writer: Signs of Polypus.

of the old writers, though they were ignorant of the true cause.

1. In numerous cases, I have found every second beat of the pulse, and in several every second and third beat, *permanently* dropped; whence the frequency was only half, or one-third, of the natural standard. In the whole of these cases, with two exceptions, I found that though the deficient beats were not perceptible in the pulse, they were audible in the heart, being occasioned by ventricular contractions too feeble to propagate an undulation into the arteries: whence I have no doubt that such cases constitute the bulk of those recorded by writers, before the discovery of auscultation, as instances of remarkably slow pulses:—viz. 40 or 30 per minute. In the two cases of exception alluded to, each presenting a pulse of 28 (two intermediate beats being dropped) the deficient beats were not perceptible even by listening to the heart on the occasions when I examined the patients, though they previously had been in one of the two. Mere slowness of the pulse, however great, is not necessarily connected with organic disease of the heart. I am acquainted with one instance in which the pulse fell to 30 after hypercatharsis following a fever, and several months elapsed before it returned to its natural standard. I have at present a patient whose pulse has fallen from 60 to 42, from over-study producing cerebral exhaustion.

2. A more common variety of intermittence, almost peculiar, when permanent, to disease of the heart, is one attended with inequality: namely, one stronger beat of the pulse is followed by one, two, three, and in some cases even four smaller and barely perceptible beats, each attended with an audible contraction of the ventricles. These minor beats are sometimes unequal in size and force as compared with each other, and regular in their intervals.

13. *The pulse larger at one wrist than the other.*—This may proceed from an irregular distribution of the radial, or other arteries of the arm; from aneurism, or compression of an artery by a tumor, and I have often seen it occasioned by extending the arm forwards or across, when the patient wore a coat or corset too tight at the axilla.

*Cardiac cause.*—The same may be occasioned by contraction of the ori-

gin of one subclavian artery, resulting from disease of the aortic coats, usually connected with dilatation or aneurism of that vessel.

Such are the common varieties of the pulse resulting from ordinary causes, and such the corresponding varieties from disease of the heart. On comparing the two, the resemblance will appear striking; and, if so, it is obvious that the pulse cannot possess its legitimate value as a sign of ordinary disease—nay, that it will often possess a dangerously fallacious quality, unless due allowance be made for the modifying effect of accidental coexistent disease of the heart. I have repeatedly seen untoward consequences result from this complication being overlooked. The occasions demanding the allowance in question are not few; for, since auscultation has enabled us to detect even slight degrees of cardiac disease, once veiled in impenetrable darkness, or dimly seen through misty conjecture, these affections have been ascertained to constitute a class incomparably more numerous than was formerly imagined, and presenting endless complications with other diseases.

I am not without hope that the comparison which has been offered, may enable us, by removing some of the causes of ambiguity and fallacy, to assign to the pulse in general a certain number of well-defined and easily appreciable characters, each referable to tolerably distinct and uniform causes: and that we may be thus protected, on the one hand, from the old-fashioned labyrinth of transcendental distinctions, and, on the other, from the meagreness of a dependence, with Heberden, on frequency alone. Should such be the result, it cannot fail to contribute a mite to the amelioration of practical medicine: at least, I can frankly say, that since I have obtained an insight into the pulses of diseases of the heart, and, by the reflected light thus obtained, have acquired a clearer view of pulses from ordinary causes, I have consulted this sign with a facility, a confidence, and a success, to which I was previously a stranger. I am prepared, however, to expect that a considerable period must elapse before the cardiac pulses which I have described will be universally admitted.

March 27, 1838.

CONTRACTIONS OF THE LIMBS  
FROM SULPHATE OF IRON.

*To the Editor of the Medical Gazette.*

SIR,

IF you consider the accompanying case to be of sufficient interest, you will oblige me by affording it a place in your valuable journal.—I am, sir,

Your obedient servant,

O. A. MOORE.

York, May 18, 1842.

Joseph Green, æt. 14, a healthy looking boy, though not strong, residing in this city, has been employed in the laboratory of an extensive and respectable firm of wholesale druggists for about two years, where his father has been similarly engaged for several years past. Has enjoyed generally good health, though he occasionally complained of weakness in the limbs, &c. which were ascribed to his "growing." He was engaged during Saturday, May 7th, and the following Monday, and part of Tuesday, in picking the crystals from the strings in a wooden vessel where sulphate of iron was placed to crystallize—another boy being similarly engaged with him—occasionally putting his hands into the mother liquor, which he complained "cracked his fingers."

On the Tuesday, at 3 P.M., he was attacked with headache, and sickness, which continued for two hours (he having vomited two or three times), when he first noticed contractions in his arms, hands, and feet. He describes that his arms were bent at the elbows, and his fingers drawn towards the forearm by flexure of the wrist. His knees were slightly flexed; but his toes were drawn upwards rigidly towards the ankle. His mother proceeded to rub the limbs, which were very painful, especially the feet; the latter were put in warm water. About 8 P.M. he was much worse, the pain being, in the calves of the legs and feet, "distracting." He had also colicky pains in the abdomen.

The following morning a surgeon was called in, who ordered a powder (the bowels had not been relieved), which operated briskly by vomiting and purging; he directed that a dispensary recommendation should be obtained. This he accordingly did; and about 1 P.M. on Wednesday, I accom-

panied Mr. Wilson, the resident medical officer, to see him.

*Symptoms.*—We found him in bed, and unable to stand with ease, though his feet were not then contracted, but rather "stiff." His hands were completely flexed, as before described; yielding to forcible extension, but immediately returning to the same condition as before. Pulse not much accelerated. Rather feverish, with a thickly-furred tongue. Bowels relieved by the powder. Pain in the body and feet abated. Ordered—

Pil. Coloc. Co. gr. x. st. sd.; and the saline mixture with Magnes. Sulphas. Hands to be fomented with mustard fomentations.

12th.—Much improved. Hands quite natural, and were speedily relieved by the fomentations. No pain in the limbs; stools watery and offensive; weakness and pain in the back; slight febrile symptoms; tongue cleaner.

18th.—Up to this time has continued to improve, the aching pain in his back being the only symptom requiring notice. He has returned to his work.

*REMARKS.*—His mother informs me that the water he drinks is brought in buckets from the Ouse; and I find, on inquiry, that none of his fellow-workmen have ever been similarly affected. On application to one of the partners, I was most liberally provided with samples of the salt, and mother liquor from the trough, which I also examined; and the result of a careful analysis (assisted by my friend, Mr. Thisselton, of this city) is, that there is not the slightest appreciable quantity of any salt of lead in the solution. The salt itself is a beautiful example of the peculiar pea-green of the proto-sulphate of iron.

It will be noticed that, in the case of the foot, the extensors were not affected, but the flexors, in this instance; if we are to credit the mother's account, who states that she rubbed the "leaders which had started up in the foot."

The facts of the case were as above stated. I offer no conjecture as to the remote cause; though certainly the coincidence of their occurrence, with the continued application of solution of sulphate of iron to the hands, leads me to look to the latter as their cause.

The boy had not been employed for some time previously with any metallic salt.

## HÆMORRHAGE FROM EXTRACT- ING TEETH.

*To the Editor of the Medical Gazette.*

SIR,

A LATE fatal case of hæmorrhage succeeding the extraction of a tooth, although by no means an unprecedented occurrence, has excited much attention, and some alarm also, both in and out of the profession; and elicited many suggestions for the management of similar cases in future. Every body seems to have his own favourite plug, or wonder-working styptic; you will therefore, I trust, excuse me for mentioning my plug, which is nothing more nor less than the extracted tooth itself: reinsert it carefully, and keep it *in situ* the best way you can, and as long as may be necessary. I have myself had occasion to do this only once or twice in the course of a pretty long practice, when the bleeding had become alarming from its continuance, and effect upon the circulation; but, from the little experience I have had, I am disposed to think that the extracted tooth fits the bleeding cavity better than either cork or sponge, or any thing else that has yet been proposed.

Upwards of twenty years ago an interesting case of death from hæmorrhage following the extraction of a tooth was published in the *Medico-Chirurgical Transactions*, which I regret I have not an opportunity of referring to; but, so far as my memory serves, Mr. Blagden, surgeon to the late Duke of Kent, saw the patient the day after the operation, and failed to arrest the hæmorrhage. Some days afterwards Sir Benjamin Brodie used the actual cautery, with little advantage; and ultimately tied the common carotid, which also failed. The patient, a young man, died next day; being about a week after the extraction of the tooth.

This, like the recent fatal case, made a good deal of noise, and many nice things were proposed as *cures* for such untoward events; and I am not certain that the method which I now advise was not also recommended. But when the hæmorrhagic diathesis prevails, the individual is at all times in a perilous state, and only requires a slight wound

of any kind to be inflicted, to bring his life into immediate danger. To ascertain the diagnostic symptoms of this diathesis, and how best to improve the general health before having recourse to even one of the minor surgical operations, where this vitiated condition is suspected, appears to me far more deserving of our attention than how to stop a bleeding from the socket of a tooth, although it is doubtless the duty of the medical profession to be prepared for such accidents.—I am, sir,

Your obedient servant,

ARCH. BLACKLOCK,  
Late Surgeon, R.N.

Dumfries, May 14, 1842.

## CASE OF POISONING BY SUL- PHURIC ACID.

*To the Editor of the Medical Gazette.*

SIR,

IF the accompanying case of poisoning by sulphuric acid possess sufficient interest, I shall feel obliged by its insertion in the *MEDICAL GAZETTE*.

I am, sir,

Your obedient servant,

J. SCOFFERN, M.D.

Lecturer on Chemistry at the Aldersgate  
School of Medicine.

14, Alfred Place, Brompton,  
May 24, 1842.

On Friday morning, 20th inst., I was called in by Mr. Harness, a general practitioner, of Brompton, to visit Jane Speller, a servant girl, residing at No. 1, Pelham Crescent, Brompton, who was supposed to have taken poison. On my arrival, I found her lying on the floor of her bed-room, with a black frothy matter issuing from her mouth; her extremities exceedingly cold; pulse almost imperceptible; breathing laboured and irregular. Her cap, and some other articles of dress, were stained with black marks, similar to those produced by sulphuric acid. I immediately ran to the kitchen, procured a quantity of whitening, which I mixed with milk, and administered copiously. After this treatment she rallied considerably; a copious vomiting of streaky mucus supervened, and, by the aid of stimulating embrocations, warm bricks, &c. the extremities were brought to the natural temperature.

*Further treatment*, 2 o'clock. A.M.—Small quantities of mutton-broth and

arrow-root were given by a teaspoon, at frequent intervals; and the following injection was administered:—

*R. Jusculi Ov. ʒij.; Tinct. Opii, ℥x. M. ft. enema statim injiciend.*

Shortly after the administration of this enema, there was discharged about a pint and a half of black grumous matter, perfectly neutral as it regards the test of litmus paper.

The mutton-broth and arrow-root were returned almost immediately; but the yolk of an egg, administered in the entire state, was retained.

4 o'clock, P.M.—Rept. Enema.

*R. Tinct. Hyos. ʒij.; Cetacei, ʒij.; Vitell. Ov. Rec. tere bene in mortario; misce cum q. s.; Aq. Cinnamon.; Ad lagenam, ʒvj.; implend. de qua capiat ægra cochleare magnum partitis dos, omnia hor. 2.*

This enema, like the last, caused a copious discharge of black foetid matter, and afforded so much relief that it was determined to persevere in the treatment. The mixture, however, did not afford the relief anticipated, and, therefore, was not persisted in.

6 o'clock.—Breathing and swallowing more easy; but the stomach still in an intense state of irritation, rejecting every thing; violent desire for cold drinks; pulse nearly imperceptible.

V. S. ad uncias iv.

Blood, at first, flowed with difficulty; afterwards more readily. Under this treatment the pulse became more full.

8 o'clock.—The patient now slept, on the whole, soundly; breathing not very difficult; occasionally she was awakened by violent fits of coughing.

I remained with her all the night, and did not remark any manifest change of symptoms. About 5 o'clock on Saturday morning, she spoke to me, regretting the act she had committed, and hoping that her life might be saved. The same desire for cold mucilaginous drinks remained, and was freely gratified.

Saturday morning, 10 o'clock.—The administration of another enema was thought desirable, and was attended with a marked improvement in the general symptoms.

2 o'clock.—Great pain over the epigastric region, increased on pressure; general symptoms of severe gastritis; to relieve which, there were ordered—

*Hirud. xvij.*, followed up by an application of hot turpentine.

She now rallied considerably, and was rather disposed to become loquacious; her mental faculties entirely perfect.

6 o'clock.—Increased difficulty of breathing, to relieve which was ordered,

*Cataplasm sinap. faucibus externis applicend.*

This measure, however, was not followed by any amelioration of symptoms; on the contrary, the pulse still became more imperceptible; the breathing more difficult. She sank deeper in the bed, snatched at imaginary objects, and betrayed an alarming restlessness.

*R. Tinct. Opii, ℥xv.; cum pauxillo mucilaginis et vini xerici administrand.*

This produced a state of rest, from which she did not awake until half-past three. About this time I saw her: she described herself as free from all pain, and as having passed a comfortable night. At her request I gave her a little arrow-root from a tea-spoon, which she partook of with avidity, occasionally uttering epithets of satisfaction; then suddenly ceasing to swallow, as if desiring a little rest, she sunk back upon the pillow, and died without a struggle.

*Sectio cadaveris.*—Yesterday evening, in compliance with the coroner's warrant, I instituted a post-mortem examination, the appearances developed by which were as follow:—

Lips excoriated, and much blackened; œsophagus congested, and also blackened; cardiac and pyloric ends of the stomach intensely inflamed, blackened, and excoriated; middle portion of the stomach not so much affected; duodenum slightly affected; all other portions of the intestinal tube nearly filled with flatus; kidneys very much inflamed, *exerting an acid reaction on litmus paper*; left ovary contained a corpus luteum; right ovary a clot of blood; uterus, about the ordinary size, somewhat congested, and containing some purulent or mucous fluid adhering to its mucous membrane.

*Chemical analysis.*—As a matter of curiosity, I analyzed a minute portion of the cap, which bore evidences of the poison, and found the results to be most satisfactory. Distilled water, in

which the piece of linen alluded to had been digested, copiously precipitated chloride of barium and another piece of cap, on being treated in a test-tube, gave off an abundance of sulphurous acid gas, evidenced by the blue colour produced on transmitting it through a mixture of iodic acid and starch. This latter test I consider to be more available than any other for the purpose of discovering sulphuric acid in organic mixtures. Finding that the kidneys, when cut into, afforded a fluid which reddened litmus paper, I was anxious to see whether I could obtain from them evidences of sulphuric acid: this question I settled satisfactorily in the affirmative by means of Devergie's test, just alluded to: thus demonstrating its great value, and supplying an interesting fact to the physiologist.

### MEDICAL SCHOOL EXAMINATIONS.

THE improvements of late years made in the system of medical education have been great; and that the advantages arising therefrom are commensurate, is shewn by the higher professional attainments possessed, and the better character borne, by the general body of students at the present time, as compared with those of any previous period. But while we are far from insensible to these advances, and while we yield a willing assent to much good that has been already done, we cannot be so blind as to overlook the fact, that much more still remains to be accomplished in various ways. We would refer to one department only; and we think it evident that some glaring defect must exist in a system of examina-

tions which is attended with so large an amount of cramming as is now prevalent with the candidates for medical diplomas. We do not exaggerate—probably we understate the truth—when we affirm that at least five-sixths of the men presenting themselves for the examinations of the College and Hall, have undergone, for a greater or less period, the degrading process which has obtained the appropriate designation of *grinding*. So fashionable has this become, that it is regarded as an almost necessary routine; and the few who are daring enough to omit it are esteemed reckless and presumptuous persons, are thought to expose themselves to a needless risk, and, indeed, they are almost pitied for their foolhardiness by the more numerous class. Nay, we have even known teachers in schools acquiesce in the same opinion, and recommend their pupils "to grind," as the securest and most easy method of obtaining their diploma. We do not say that all the men thus preparing themselves are unacquainted with the principles of their profession, or have neglected the proper employment of their time during the period of their education. We are fully aware that many well-informed men are induced to have recourse to these means, from a sort of sympathetic influence, or from a terror of unfair and catch-questions requiring certain fixed answers which are to be found only in the note-book of the private tutor. The latter is a most influential cause, being sedulously and deeply impressed on the minds of students by the many whose interest it is to keep alive such an apprehension. It is, however, certain that great numbers, who have completely idled away the whole period of their education, and who are totally ignorant of medical science or practice, are, by these means, in a short space of time—six months, or less—worked up to the

required point, pass with credit, and are complimented on their extensive information.

To propose an effectual remedy for a system so deeply rooted, may be no easy matter. So long as it is possible to find an easier by-way to a degree, we cannot expect the careless followers of medicine to be voluntary toilers on the heavy and laborious road to science. It is, nevertheless, a duty, to check, as far as we can, these injurious customs, and to give inducements to the more honourable and useful study of the profession.

The examinations and distributions of prizes in the schools on the several subjects of medical education, which have been often before adverted to in these pages, have doubtless had much influence in encouraging the assiduity and awakening the zeal of the students generally, and especially of those who enter into competition; and it is on this account that their more extended influence is to be desired. If they have proved beneficial on a small scale, why should they not be more largely tried? At present, their advantages are very limited, inasmuch as they affect directly but a small proportional number. Even in the larger schools of this metropolis, it constantly happens that not more than five or six are found willing to contend in each subject, and not unfrequently one is allowed to walk uninterruptedly over the course. To obtain the full benefit which these competitions are capable of affording, it is necessary to render them compulsory—to require that each candidate for the diploma or license to practise should present certificates of having engaged, and satisfactorily acquitted himself, in a certain number of preliminary examinations. It is a system easily put in execution, and one which, we doubt not, would be attended with

a most favourable result. By it would be ensured, in a greater degree, the application of the student through a more extended course of time, and it would present the most effectual obstacle to the possibility of obtaining a degree by temporary cramming. The inefficiency of the curricula and registrations now in force to ensure the diligence of the student, is notorious. They really offer no check at all to inattention and irregularity. How far more effectually would the object they have in view be attained, by obliging the students annually to engage in the examinations held at the several schools. If all were obliged to compete, we believe there are very few who would not be induced to take some pains to maintain a respectable station.

We often hear it urged, as an objection to these examinations, that they tend to divert the attention of the aspirant from obtaining a sound and practical acquaintance with his profession; leading him to trust in book knowledge and theoretical information. This opinion is founded on the erroneous supposition, so very prevalent, that an acquaintance with the literature is incompatible with a study of the practical department of medicine—an opinion the more willingly assented to by many, as furnishing a ready excuse for the neglect of the former. We believe this idea to be one of the great hindrances to the advancement of medical science, encouraging as it does men to remain in ignorance of the principles of their profession, and leading them to act as mere mechanical agents, without inquiring into the causes of disease and the operation of remedies. As an argument in the present instance, therefore, we deem it untenable; indeed, it is opposed to the fact, that the students, who are best informed in the theory of medicine; are usually the most sedulous and suc-

cessful in obtaining information at the bedside of the patient.

It will perhaps be said that by the course proposed too much of the student's time would be employed in obtaining an acquaintance with those subjects (as botany), which have no direct connection with the practice of medicine. In answer to this objection we would simply reply, that, if to gain a competent knowledge of such branches be deemed a waste of time, why should they be retained in the curriculum of medical education at all? Why should the student be required to engage himself in the prosecution of a study the competent knowledge of which is not deemed important?

One of the evils of the present system of examinations for a diploma is, that the candidate is required to be at one time prepared with a great many subjects of a very comprehensive nature. Despairing of ever attaining to a moderate knowledge of all, he shrinks from the attempt as an Herculean task, and to avoid the disgrace of rejection has recourse to the alternative of working up a mass of definite answers to the questions most likely to be put. Feeling this to be the easiest, and at the same time fancying it the safest method, he is induced to rely entirely upon it, and idling nearly all the time appointed for his education, trusts to the last few months to fit him for his examination, and goes into the world possessing his license to practise, but in every other respect utterly unprepared.

Now if, at the conclusion of each session, all were obliged to evince a competent acquaintance with the subjects that had engaged their attention during that period, the necessity of requiring knowledge on so many branches at any given time would be diminished, and the constant attention of the student more certainly enforced.

By the repeated recurrence of examinations, men would at any rate be obliged more frequently to prepare their subjects, and at the same time that the probability of their retaining some information would thus be increased, a greater chance would be afforded to them of forming habits of application, and acquiring a relish for the study of their profession.

The advantage of rendering these school examinations, or something of the same sort, compulsory and universal, would be equally manifest as applying to the nature and intent of the examinations themselves. They would thereby be rendered much fairer tests of the relative merits and real deserts of the candidates than they at present are. For, though it be true, as a general rule, that the best informed men in the class are included among the number of those who contend for prizes, such is not always the case. We have, in repeated instances, known the most industrious and proficient unwilling, from a feeling of distrust their own powers, or some other cause, to enter the lists. On the other hand, when so few compete, the honour, though perhaps not the less deserved, is apparently diminished. Of four candidates, the least successful is apt to be looked upon as the *last* of that number, while the credit of being the fourth proficient in the class is overlooked. By a greater number of opponents the honour of success would be enhanced; while the demerit of failure would be diminished by the increased proportion of those who shared it. Again, the present system is liable to the objection, that some men, by devoting all their time and energies to one or two particular subjects, are enabled to gain the undeserved reputation of beating their more experienced compeers, whom duty or inclination induces to labour in

a wider field. On this account, a sort of monopoly of prizes is carried on in the schools, which, with other causes, interferes much with the effective operation of the examinations as they now stand, and even tends to bring an opprobrium on the system altogether. These hindrances to their beneficial action being entirely dependent on the partial manner in which they are carried out, would necessarily be obviated by the more universal application of them which we propose. They have already done much good, by exciting an honourable emulation among students, and promoting greater assiduity in the study of medicine; and we cannot see any good reason why this desirable influence should be confined to so small a number as it now is, and not extended to the general body. No inducements in the way of prizes, and nothing short of a compulsory plan, can effect the full advantage which these competitions are capable of producing: while the option is given to the student whether he will engage in them or not, it will be always found, as at present, that the devotees to idleness and gaiety will greatly outnumber the aspirants to honour and distinction.

The senate of the London University, acting partly upon this principle, require a certificate of the candidate's having passed preliminary examinations, before he is allowed to present himself for his degree; and thus far their project is good: but they also fall into the error of requiring a high degree of knowledge on so extensive a range of subjects as to intimidate men from the attempt, or induce them to have recourse to grinding as a means of preparation, which is carried on in the same manner, though to a less extent, as for the College and Hall.

## KING'S COLLEGE HOSPITAL.

## CASES OF APOPLEXY CONSEQUENT ON SYPHILIS:

## WITH CLINICAL REMARKS

By DR. BUDD,  
Professor of Medicine.

DURING the past year three patients have been brought into the hospital, under my care, with hemiplegia, the result of an apoplectic seizure occurring in the advanced stages of constitutional syphilis. These cases made a greater impression on me, in consequence of their resemblance to two cases which strongly arrested my attention several years ago. Two young men, with whom I was well acquainted, were struck with apoplexy about the same time. They were of naturally robust constitutions, but had both, for some time before the seizure, been affected with syphilitic rupia and periostitis. There could be no doubt that the apoplexy was caused by the syphilis, or by the mercury given to cure it. The former hypothesis seemed to me the more probable.

Of the three cases that you have seen in the hospital, the first in order is that of James Wetherall, æt. 27, who was admitted on the 21st of April, 1841. He told us that his health was very good until five years ago, when he had chancres, which were treated by mercury. After this he had ulcerated sore-throat, for which he was out-patient of St. Bartholomew's two or three months. About four years ago he entered the army, and six or seven months afterwards became affected with very severe headaches, and pains in the arms. On account of these ailments he was several times in the regimental hospital; and on one of those occasions, while in the hospital, he had a seizure, in which he fell down insensible. He soon regained his consciousness, and then found that he had lost the use of his left side, and that his face was drawn to the right. His speech also was greatly altered. The arm and leg were at first completely palsied, so that he could not move a finger or toe. At the end of some months the power of the arm had returned partially, and he was able to walk, but with lameness.

About twelve months ago had slight numbness in the right hand, and indistinctness of speech; symptoms which were removed by cupping. Has since had four or five slight attacks of the same kind.

About a month before his admission to the hospital, œdema of the legs supervened on his other complaints.

When brought under our notice, his face was puffy and bloated, and his legs were slightly œdematous. The urine was abun-

dant, and highly charged with albumen, which was deposited in solid shreds on the addition of nitric acid.

The left leg was permanently contracted at the knee, and he made great complaint of pain when any attempt was made to straighten it. It had been bent in this way, he said, for a month. The left arm was weak, but he could use it with tolerable freedom. The sensibility of the arm and leg were unimpaired. There was no perceptible paralysis of the face: the tongue was protruded straight, the pupils were equal, and the senses were perfect. His intellect was, however, somewhat impaired: his answers were slow, and his speech indistinct. He was free from headache or giddiness.

He had a large node on the shin of the left leg, and suffered pains in the limbs, which were worse at night. There was great tenderness on the humeri, and on the lower part of the left thigh-bone.

He complained of thirst, but his appetite was good, and his bowels regular.

His symptoms, then, were referrible, in part, to disease of the kidney, which seemed to be of recent occurrence; partly, to the old lesion of the brain; partly, to the periostitis, which still existed.

The dropsy and thirst were, no doubt, connected with the albuminous condition of the urine.

The weakness of the left arm, the indistinctness of speech, and the slowness of intellect, were the consequence of the apoplectic seizure.

The pains in the limbs, and the contraction of the left leg, of the periostitis still existing.

I was led, at first, to refer the contraction of the left leg to the cerebral lesion, but a closer examination convinced me that it depended on periosteal inflammation of the lower extremity of the femur. While physician to the Dreadnought, where syphilitic periostitis is very common, I met with several instances where contraction of the knee-joint, or elbow-joint, was the consequence of a node, or of periosteal inflammation under the flexor tendons.

On account of these latter symptoms I gave him gr. v. of iodide of potassium three times a day. The result was as I expected. In a few weeks the pains in the limbs had disappeared, and the leg was straight. He walked, however, with some lameness, on account of a slight degree of palsy of that leg, which persisted.

He left the hospital much improved in condition. The oedema of the face and legs had disappeared, but the urine continued albuminous.

The second case is that of Henry Harrison, set. 47, clerk in an office, who was

admitted into the hospital on the 14th of May, 1841, on account of periostitis.

He complained of pains in the limbs, worse at night, and there was great tenderness, with some pitting, along the tibia.

He ascribed his ailments to syphilis, which he contracted ten years before. He had not been intemperate in drink, and before he became infected had enjoyed good health. He took mercury, and the chancre healed, but about three months afterwards a scaly eruption came out on the scalp. It was about six months after the healing of the sore, as well as he can recollect, that he first suffered pains in the limbs, which were worse at night.

About seven years ago (three years after the chancre) he had sores (rupious) on the scalp, and very severe nocturnal pains in the head. After these symptoms had continued some time, he had a seizure, attended with loss of consciousness. On recovering his senses he found that his right arm was so weak that he could scarcely write, and that the right leg was also weak. He does not recollect his face being drawn.

The strength of the arm and leg gradually returned, and at present the only trace of the palsy is slight weakness of the right arm. Says that his memory has been impaired ever since the seizure.

The periosteal pains he now complains of came on three weeks ago.

He was ordered five grains of iodide of potassium three times a day, and soon left the hospital, cured of his periostitis.

The third case is that of William Dodd, set. 26, smith, who was admitted into the hospital the 2d of Dec., 1841, on account of headache and paralysis of the left arm and leg.

He stated that his health was uniformly good until two and a half years ago, when he contracted syphilis. The chancres healed at the end of two months under the use of pills, which made his mouth sore. About four or five months afterwards, he had sore throat and an eruption on the skin, which, after lasting some months, were cured by mercury. These ailments were succeeded by headache, and by pains in the limbs, which were worse at night; and about last Christmas, by sores on the legs.

The headache was very severe, and, like the periosteal pains, was worse at night.

These symptoms continued until five months ago, when he had a seizure, in which he lay almost unconscious for about an hour. On recovering his senses he found that he had lost the use of the left arm and leg. The tongue and the left side of the face were also partially paralysed. At first there was numbness in the paralysed parts, but sensation was soon restored. After the seizure the headache was less severe than

before, but he has suffered from it, at intervals, ever since. The sores on the legs healed, and the pains in the bones were removed by medicine (iodide of potassium?) of which he does not know the nature.

At the time of his admission, he was free from pain in the limbs, his complexion was clear and florid, and he had no eruption, except between the eyebrows, where there was a copper-coloured spot, about the size of a sixpence, covered with very small and thin, greyish, scales. He had very little voluntary power in the left arm, and walked awkwardly and with difficulty, on account of the paralytic affection of the left leg. The pupil of the right eye was larger than that of the left; but there was no paralysis of the face or tongue.

The left arm was contracted at the elbow and wrist, and the fingers drawn in towards the palm. It required considerable force to extend the fingers or the arm, but an attempt to do so caused no pain.

The left leg, while he lay in bed, was rigidly extended; and the foot a little turned inwards by contraction of the *tibialis anticus*.

He had no twitchings in the palsied limbs, but told us that when anything occurred to startle him the left hand became more firmly clenched. When he was uncovered, the left arm and leg shivered violently, but the right were perfectly still. (This circumstance was witnessed several times during his stay in the hospital).

The sensibility of the palsied limbs was unimpaired; and their muscles were very little, if at all, wasted.

He complained of headache, chiefly on the right side.

He was purged for a day or two; and then ordered five grains of iodide of potassium three times a day. The iodide produced more than its usual constitutional disturbance, and we were obliged to discontinue it. It was again resumed; and on the 22d, while he was still taking it, he had an epileptic fit, which was followed by severe headache and by feverishness. On account of this, the iodide was again left off, and he was ordered to be bled from the arm and to take brisk purgatives.

On the 4th of January he had another epileptic fit, which lasted nearly an hour. During the fit, the left limbs shook violently, but the right were quiet; he was perfectly unconscious, and foamed at the mouth.

After this he was ordered five grains of blue pill, night and morning. Under this treatment the spot between the eyebrows disappeared, and the headache became less severe.

He left the hospital on the 2d of February, with the palsy just as it was at the time of admission.

In this case the patient was too young to

allow us to suppose that the apoplexy was caused, as it often is in advanced life, by degeneration of the arteries of the brain; and he assured us he had never drunk hard, and that he had received no blow on the head. As in the former cases, we cannot held ascribing the seizure either to the syphilis, or to the mercury given to cure it. The latter hypothesis is here very improbable. He had indeed taken mercury twice—first, for the chancre; secondly, for the sore-throat and eruption—but the mercury was not, either time, carried to salivation, and he had taken none for twelve months before the seizure. If the seizure were the effect of the mercury, it would in all probability have happened sooner after its administration. We are driven, then, to consider the apoplexy the effect of the syphilitic virus. This conclusion is strengthened by the consideration that, in all the cases, the apoplexy occurred in the advanced stage of syphilis; when the patient had been for some time affected with periostitis, and in every case but one, where no mention is made of rupia, with rupious sores.

It may be a question whether the apoplexy resulted from the immediate action of the syphilitic virus on the brain, or whether it was consequent on syphilitic inflammation of the bones of the head. Dissection, in a case of this kind, would settle the point. If the disease of the brain be the effect of that of the bones, it is most probably seated at the surface of the brain, and in contact with the diseased bone. In Wetherall and Harrison, the intellect was more affected than is usual with the same degree of paralysis—a circumstance tending perhaps to show that the lesion was towards the surface of the brain.

The cases I have related are, I think, sufficient to justify us in considering apoplexy as one of the effects of the advanced stage of syphilitic disease, characterized by periostitis and rupia.

In the case of Dodd, you have remarked many interesting phenomena, resulting, as Dr. Marshall Hall has shewn, from the high degree of irritability of the muscles of the paralysed limbs. The left leg was rigidly extended, and the foot turned inwards; the left arm was contracted at the elbow, and the fingers were drawn towards the palm, by permanent contraction of the muscles. When he was uncovered, the left arm and leg were violently shivered from the impression of cold air; while their fellow limbs were perfectly still. The impression was here the same on the two sides; but there was shivering of that side only whose muscular irritability was exalted.

The influence of emotion was also seen in

the palsied hand. Dodd told us that, whenever anything occurred to startle him, the hand, over which he had not the slightest voluntary power, became more firmly clenched. The influence here, like the impression of cold, must have acted on the two sides alike; but its effects were seen only in the hand whose muscular irritability was exalted, and which was no longer controlled by the will.

Another proof of the high irritability of the muscles of the paralysed limbs, more interesting because less frequently seen, was their being convulsed during an epileptic fit, while the opposite limbs were motionless. There is reason to believe, from the complete loss of consciousness, that during an epileptic fit both sides of the brain are affected alike. The left limbs only were convulsed in Dodd, because their muscles were more irritable than those of the right. They gave evidence of an influence too feeble to affect the opposite limbs. M. Cruveilhier has published the details of a case in which the same fact was observed. The patient, who had been many years palsied on one side, was subject to epileptic fits. During the fits the palsied limbs only were convulsed. It would seem from this that the degree of convulsion in epilepsy depends in part on the degree of irritability of the muscles; and we should expect that, as a general rule, the frame would be more convulsed in epileptic fits that occur in the morning on waking, than in those which occur in the evening, when the irritability of the muscles has been somewhat exhausted by the fatigues of the day.

## VACCINATION ACT.

*To the Editor of the Medical Gazette.*

SIR,

I SEND you the following remarks on the working of the Vaccination Act, for publication in your valuable GAZETTE, or otherwise, as you may think proper.—I am, sir,

Your obedient servant,

J. N. STEVENS,

Cornwall, May 16, 1842.

Surgeon, &c.

*On the Insufficiency of the Vaccination Act to effect the purposes for which it has become the law of the land—viz. the making the performance of Vaccination general, and thereby ultimately banishing Small-Pox from our shores.*

I believe it was generally hoped that the Vaccination Act, when once in full operation, would be the means eventually of eradicating small-pox altogether from the country; and if the good intentions of the legislature could have been carried into full

effect by the provisions of this enactment, such might ultimately have been the happy result; but I would ask, has this been the experience of the public vaccinators? As an individual who has had some little experience in the matter, I am compelled to reply in the negative; and I verily believe that my statements on this subject will be confirmed by most others who have held similar appointments—at least in rural districts. In the first place, then, I find the parties who generally avail themselves of gratuitous vaccination, although considering it of decided efficacy as a preventive of small-pox (of uncertain duration), and as greatly modifying any subsequent attack of variola, and although the *bump of philoprogenitiveness* may be largely developed on their individual skulls, I am sorry to add my experience has led me to the conviction that the anxiety they should feel for the good of their little ones is very frequently only awakened when the hideous monster (small-pox) actually makes its appearance amongst them in its most malignant form—the precursor of death and deformity to their nearest and dearest connections. At Michaelmas 1840 I obtained a vaccination appointment to an extensive district of the Helston Union, which was divided into four convenient stations for the public performance of the operation: small-pox had just then made its appearance amongst us as an epidemic, and between this time and Lady-day the applications for vaccination were so numerous that I had performed the operation successfully on nearly 400 persons; but from this date to Michaelmas, when my contract terminated, scarcely any applications were made, although, out of a population of about 7000, there must have been during the nine months a very considerable number of children who should have been operated on. But the small-pox had disappeared; and with it the anxiety of the lower orders in reference to the protection of vaccination, and, in the interim of another varioloid epidemic, they will exhibit an apathetic carelessness on this all-important subject deeply to be regretted. And this leads me, in the second place, to contend, that the intention of the legislature and the hopes of the country in regard to the ultimate object of the Vaccination Act will be alike defeated, unless there be inserted in the act a clause compelling the vaccination of all children before the age of four months, if in good health, and in default thereof the parties to be subjected to a penalty. This might be considered by some persons too arbitrary and despotic a clause, but I am quite convinced; without something of the kind is done, the grand anticipated result of gratuitous vaccination will never be obtained; and, when it is considered that this act of parliament was framed for a great individual

and still greater public good, it could not I think with reason be objected to. The effect of so many thousands of children being permitted, by the indifference of their parents, during the absence of small-pox, to remain for years without the protection afforded, and freely offered them by this act, (which assuredly without a compulsory clause will be the case,) would undoubtedly be to perpetuate small-pox to the latest generations.

### POOR-LAW QUALIFICATION ORDER.

*To the Editor of the Medical Gazette.*

SIR,

IN a letter which you did me the favour to insert in your number for the 22d ult., I dwelt upon the cruel injustice of the Poor-Law Qualification Order, in its bearing upon those members of Scotch and Irish Colleges of Surgeons who are also Licentiates of the London Society of Apothecaries. This injustice seems likely to take effect somewhat sooner than was anticipated. Before the order came into operation, the usual spring election of medical officers had, in most of the Unions, been made; and those who protested individually (as I did) against the order were reminded that, before it could personally affect them, the Medical Reform Bill of Sir James Graham, or, for a certainty, the renewed Poor-Law Bill, must pass, and would probably not be carried without a satisfactory adjustment of the rights and privileges of the various British Graduates and Licentiates. In compliance, however, with the new regulations of the Commissioners, many fresh medical districts are being formed, requiring a fresh supply of medical attendants. From these new appointments all British surgeons and apothecaries, whose diplomas in surgery are from any other College than that in London, are virtually excluded; and as it seems intended to make the situation of medical officer to a Union as permanent as may consist with the due performance of its duties, such practitioners as are shut out now will probably remain so for many years to come. If Mr. Guthrie is sincere in his liberal wish as to equality of privilege between the medical men of the three divisions of the kingdom, and if Mr. G. C. Lewis is still sensible of the propriety of that wish (see Mr. Guthrie's letter to Mr. Hovell, p. 23 of this volume), now is the time to act on their professions, and to settle the matter "in a manner which will be satisfactory" to all parties.

But the legal adviser of the Commissioners has some objections (legal, of course,) to an equality of medical privilege in respect to

the Poor-Law. How prone some men are to strain at a gnat, and then quietly swallow a camel! In the same breath with which this legal oracle denounces the "duly licensed" and "virtually doubly qualified" Licentiate of the College of Surgeons of Edinburgh or Dublin, and of the Apothecaries' Company, London, as ineligible for medical office in any Union where a practitioner, having the "double English qualification," can be procured, he admits the holder of an English degree in medicine to be qualified as an apothecary! The business of an apothecary is to advise, and supply for gain, medicines in medical cases; and whether this be done in private practice, or in attendance upon paupers, it is undoubtedly illegal unless the practitioner be qualified under the Apothecaries' Acts of 1815 or 1825.—I am, sir,

Your obedient servant,  
EDINBURGO-LONDINENSIS.

May 23, 1842.

### STATEMENT OF THE VISITING COMMITTEE OF THE COUNTY LUNATIC ASYLUM, NEAR GLOUCESTER.—1841.

IN presenting the REPORT of the ASYLUM for the past year, which forms the Eighteenth Annual Statement, the Visitors consider that they may confidently invite the public attention to the establishment under their government; and they refer to the table of admissions and discharges, as exhibiting in a most favourable view the result of the treatment adopted.

The generous regime and the nutritious diet which have always formed part of the treatment of the patients here are still persevered in; and it is with no small degree of pleasure that the Visitors find other similar institutions adopting the same means, and confirming, by the improvement in the curative results, and by the diminution of the mortality, their beneficial tendency.

During the past year, the Visitors have made a great addition to the comforts of the patients—and they trust a grand step towards a public benefit—by commencing a system of receiving into the asylum a limited number of officers of both sexes, in the double capacity of *assistants and students*, who do not entail any expense upon the establishment, whilst they devote the whole of their time and energies to its business. Those of the male to be medical gentlemen who have completed their professional education; and those of the female, young ladies

of good education and manners, and both required to remain twelve months in the asylum. They reside constantly with the patients—head their tables—join in their excursions—promote their amusements—arrange their difficulties—and act in all things as their friends and advisers. By their means the objectionable, but previously unavoidable, services of *keepers of both sexes*, belonging in fact to the class of menial attendants, will be done away with, and they will be reduced to their proper position as *servants* in attendance upon persons afflicted with ill health. This system has been commenced, and as far as such officers have been appointed, has proved very satisfactory. The Visitors have likewise during this year sanctioned—in fact, but not as a universal regulation—the total disuse of all mechanical restrictions on the persons of the insane: they have also allowed the introduction of *female attendants* to a share in the management of, and providing for, the male patients. It has ever been the practice of the medical officers to use as little restraint as was deemed compatible with the safety of the patient, or the protection of those about him; but they admit with the Visitors, that up to this time, all the patients are as securely managed, and are governed with much less difficulty and disturbance without than with mechanical assistance.

From the causes above named, and perhaps from others not at once cognizable, the asylum has, during the past year, exhibited a vast increase of good order and comfort. The exercising grounds, formerly scenes of occasional riot and confusion, with indications of mischief and destruction scattered on all sides, are now laid out as vegetable and flower gardens, and planted with fruit trees. To these, all the patients of each class and sex respectively, have constant access, and yet the productions of each are permitted to flourish, and their fruits to attain maturity. With the simple arrangement on the part of the Superintendent, that whatever the patients will cultivate and protect shall be their own, and be shared amongst them, and that those who irregularly or furtively misappropriate any portion shall be deprived of their share at the time of distribution, nearly the whole produce of each garden was this year brought to maturity, and partaken at the tables of the patients who had raised them.

Balls and other amusements, occurring in lunatic asylums, have been of late publicly mentioned as matter of admiration and astonishment. In this asylum, large parties for dancing have always been promoted; as well as dinner and evening parties, when proper, and pleasurable excursions, for many hours, in the country. Musical entertainments within the walls, and attendance on

public amusements, are of so frequent occurrence, that they constitute the practice rather than form the occasional source of astonishment in this asylum. Indeed, to so great an extent does our Superintendent endeavour to make his patients feel that they belong to the great community of mankind, and are only temporarily separated for their health's sake, that he encourages a great proportion to attend to their religious duties, on Sundays, in the places of worship in the city and neighbourhood; and induces all who can or will separate themselves from the asylum, to take their exercise in the surrounding country; whilst, to give encouragement to those who are inclined to be industrious, he employs all he can *without* the walls, in various ways, and cultivates nearly twenty acres with the spade in the fields adjoining and belonging to the asylum, with scarcely any other check upon their escape beyond the good feeling subsisting between himself and them.

The Visitors, being powerfully impressed with the conviction that the sole objects of this establishment are the cure of the patients, and the kind treatment of those who are incurable; and with the palpable fact ever before them, that the interests of the officers consist alone in these, whereby their responsibilities are diminished, their benevolent feelings and professional pride are gratified, cannot refrain from urging upon those whose relatives are afflicted with insanity to seek rather the public than the private asylum. They urge still more the taking this step in the early stage, when the disease has not been tampered with by inexperience, nor rendered hopeless by delay; for it is amongst the few regrets which the retrospect of past years affords, that the most painful cases have ever been those in which one or other of these misfortunes has befallen; while it is an acknowledged fact, that of those who are sent within two or three weeks of the commencement of the malady, nine-tenths are cured.

The Visitors, directing attention to the number of deaths which have occurred during the year, would express themselves strongly on the many instances in which patients have been sent from distant parts of the county, almost in a dying state—either from old age, paralysis, or consumption—in which it is not uncommon that the last stage of the disease is attended with excitement, and in which the sufferer becomes noisy. Such are not proper objects for a lunatic asylum; they do not strictly constitute insanity, but are cases of delirium attendant on exhaustion, which cannot be otherwise than exasperated by the exposure to a long journey, and the distress of being thrown amongst strangers, and which, moreover, cannot be relieved after their arrival.

MORAL TREATMENT OF THE INSANE.

IN what does the moral treatment of insanity consist? It may be said to consist in encouraging habits of self-control, in gently exercising the faculties of the mind, especially those not involved in the disease, in affording scope for the pursuit of useful employments, in gratifying innocent tastes, and bringing to bear on excited feelings and eccentricities the influence and example of sound minds. For prosecuting such treatment something more is required in an asylum than provisions for the safe-keeping of its inmates. The scholar should have his library, the artist his studio, the agriculturist his farm, the artisan his implements, and every one, society, and the means of recreation and amusement. Opportunities should be afforded for the inmates leading, so to speak, a rational life. An epitome of the world without should be presented to them, wanting, as much as possible, the sources of agitation and excitement in operation there.

I have endeavoured to keep these objects steadily in view. The inmates have been encouraged to engage in such pursuits as were congenial to their tastes; and already that system of in-door occupation has been begun, which, I trust, will form a conspicuous feature in the extended establishment. In excursions to the country, visits to public places, and to relatives at home, efforts of self-control have been beneficially called forth. Meetings of the inmates, for various

purposes, have been held, where the influence of example, and the restraining effect of society, have been exemplified. I allude to the daily attendance in chapel,—to concerts,—to meetings of a convivial nature,—and to others in the winter evenings, when, with the aid of a magic lantern, some information on interesting subjects, and no little amusement, was afforded. Daily religious services might, at first, appear open to the objection, that as religion is the cause of insanity in some, and is the subject of delusions in others, it ought not to be made a frequent subject of attention in an asylum. But experience leads us to draw a distinction between the effects of it presented to the inmates as a body, and as individuals. It may be advantageous, and certainly not hurtful, to place them in conditions where a certain restraint must be imposed on their demeanour, and religion is exhibited simply as the page of truth exhibits it, while it might prove positively injurious to attempt by arguments or reasonings, however cogent, addressed to individuals, to combat their gloomy or perverted views. Attendance in the chapel forms an epoch in the day,—it tends to give a new current to thoughts usually morbid; and it is not to be forgotten, that there are, among the inmates of an asylum, those who entertain the justest views of religion, and are, therefore, entitled to the enjoyment of all its privileges.

Every day is adding to the triumphs of moral over physical restraint, in the treatment of the insane. Whether we are yet prepared to dispense with the latter—in the

sense of personal restraint—in all cases, I do not presume to determine. To diminish its amount is, however, now the object of all engaged in the treatment of the insane; and, as in other cases, it is by the accumulation of facts, and the details of varied experience, that correct views are to be acquired on what still remains disputed regarding it. For eighteen months I have not considered it necessary to use personal restraint on any occasion during the day. In one case, (a suicidal patient,) I have been reluctantly compelled to make use of it during the night; but with a larger staff of attendants, or a building constructed on the plan of the new establishment, I would have been enabled to dispense with it even in that instance.—*Dr. M'Kinnon, in Report of Edinburgh Lunatic Asylum.*

### MORAL MANAGEMENT OF THE INSANE.

THE general or moral management of our inmates has not differed since our last report. Music parties were introduced during the winter evenings, and evident benefit, as well as cheerful amusement, resulted from their adoption. The systematic employment of the patients has also proceeded with unabated or rather increased vigour. The proofs of this statement are to be found in the appended work-accounts, the state of the grounds, and the appearance of the crops. Indeed so propitiously has this system operated, that it appears not only to have superseded the use of restraints in many of those cases in which it was once conceived to be requisite, but has also modified the necessity for that rigid supervision which had been supposed to be the only alternative of coercion. In no one instance has the latter been resorted to during the last year; nor has the occurrence of any unfortunate casualty alloyed the gratification we enjoy, when contemplating this overthrow of "the iron rule of ancient usage."—*Report of Northampton Lunatic Asylum, 1841.*

### LIME MOXA.

DR. OSBORNE has availed himself of the high temperature produced by lime in the act of slaking, for the purpose of a moxa. Some quick lime in powder, to the depth of about half an inch, is placed upon the skin inside a *porte moxa*, or a strip of card bent together, and tied so as to form a circle. Some water is dropped on and mixed with it. In about two minutes the mixture swells and becomes dry, and at the same time a high degree of heat is produced, which, according to some experiments, may amount to 500°

Far. This moxa Dr. Osborne considers to be superior to all others; first, from the intensity of the heat, which, by using a larger bulk of lime, may equal the potential cautery; and secondly, from its convenience, not requiring the assistance of any heated substance, and being unaccompanied by the emission of sparks or smoke, which create terror in the mind of the patient. When the quantity of lime applied is smaller than above mentioned, or not kept on long, the result is an appearance resembling that produced by acetic acid, and a thick crust is formed, which separates according as the new skin is perfected underneath. When, however, the quantity is as large or larger, and kept on as long as the heat continues, then a complete destruction of the skin ensues; and thus issues may be made of greater depth, and in a much shorter time, than by the usual escharotics.

In order to ascertain the depth to which this moxa acts, he applies it on the surface of an egg, and then observes the thickness of coagulated albumen formed underneath. This shows the extent to which the serum may be coagulated in the vessels of the part, and which is subsequently separated by ulceration as a foreign body; but the beneficial action of a moxa does not stop here: its superiority as an escharotic or counter-irritant, according to Dr. Osborne's view, consists in this, that the heat produces a contraction and change in the action of the vessels of parts over which it is applied, with great excitement of the absorbents, enabling them to return to a state of health after the failure of all other means, as may be seen from the cases related in Larrey's work on this subject, and as is well known and acted on by veterinary practitioners. In one case, at Mercer's Hospital, it was productive of a very decided change. A female laboured under the symptoms of ulceration of the upper part of the rectum and sigmoid flexure, for above a year, and had constantly most severe pain in those parts on passing her motions, which were accompanied by discharges of purulent and sanious matter. On being examined, the rectum and lower part of the colon were free from contractions, and the fecal masses which occasionally passed, although productive of great suffering, yet showed that the passage was not considerably narrowed; a lime moxa, which extended to about the size of a crown, was applied over the sigmoid flexure, and was immediately followed by a diminution of pain and an almost complete cessation of the discharge; and before the ulcer produced by the moxa had filled up by granulations, all the symptoms of the internal ulceration had entirely disappeared. In a case of commencing softening of tubercles, and in another apparently of purulent infiltration

after pneumonia, its effect in putting a stop to the ulcerative process was most decided.

In a case of hip-joint disease, in which there was great pain, and consequently loss of sleep, the patient slept well on the following night, and in a few days gained much power over the limb. And in another case of the same disease, which had proceeded to destruction of the joint, and extensive enlargement of the parts around it, a copious discharge of the moxa was followed in a fortnight by a complete subsidence of the enlargement, and a corner of the ulcerated surface is now kept open as an issue, the remainder being allowed to heal under a water dressing. It is to be observed, that the size of the ulcer formed is always much larger than that of the lime applied, in every case having at least twice its diameter.

When the lime is prepared from calcareous spar, the heat produced on the addition of the water is sudden and intense, and the pain is proportionately urgent. For ordinary purposes, however, well selected pieces of lime, from a lime-kiln, answers well if *fresh*, but not otherwise.—*Dublin Journal of Medical Science*.

### MULTILOCULAR ANEURISM OF THE THORACIC AORTA.

DR. LAW said the specimen before him was one of aneurism of the aorta. The patient, a man about forty-three years old, was admitted into Sir Patrick Dun's Hospital about five months since. He complained of violent pain in the left hypochondrium and epigastrium; at the time of admission this was so intense as to oblige him to rest with his knees up to his chin. The history of the case was very imperfect and unsatisfactory, as the man gave a very vague account of his symptoms, and the only thing that could be learned from him was, that he had been for the last two years subject to two kinds of pain, one of which was constant. He also had pains along the course of the ribs, and described a central point in his chest from which the pains radiated on every side. On the third day of admission he began to complain of dysphagia. On examining the chest, Dr. Law found the respiration more feeble on the left than on the right side; he complained of nipping pains in various parts of the left side, and when Dr. Law attempted to introduce a probang, he found its passage arrested about four inches below the opening of the fauces. The nipping pains, the dysphagia, and the dulness on percussion in the left side, with the fulness of the veins of the neck, led Dr. Law to suspect that it was a case of thoracic aneurism; but this was by no means certain: there

was no bruit de soufflet heard over the region of the heart, or where the aneurism was supposed to be seated, and the diagnosis remained undecided until the appearance of a pulsating tumor on the left side of the back, between the spine and the posterior margin of the scapula, set the question at rest. The appearance of this tumor was attended with increase of the pains along the course of the ribs, and on making an examination, a strong pulsation, accompanied by a distinct bruit de soufflet, was evident, the latter to be heard at various points of the chest, and masking the respiratory murmur. His breathing was tolerably free, except that it was a little more feeble on the left side, and inspiration was longer than natural, as if something was pressing on the trachea. He could not swallow when in the recumbent posture, and always took his food and drink sitting up in bed with his body bent forwards and to one side. Sometimes the difficulty of swallowing was referred to the top of the sternum, sometimes to the epigastrium, and he complained at one time of pains in the chest, at another of pains in the epigastrium and hypochondria; in fact, his symptoms were so numerous and so variable that Dr. Law was convinced that the presence of a single aneurism would not be sufficient to account for them. At the end of about four months he was beginning to feel considerably exhausted; the tumor on the back was now greatly increased in size; it had destroyed the ribs, protruded on the back, and was covered merely by the skin and muscles. When examined, it communicated to the finger a sensation as if its contents were fluid. About the end of the fifth month the man died, partly from exhaustion and partly from excessive secretion into the bronchial tubes. On dissection, a very interesting specimen of multilocular aneurism was discovered; it was of great size, and extending equally on both sides of the spine. Dr. Law said that he had omitted to mention that the pulse at each wrist was nearly equal. In front of the tumor lay the lungs, and this accounted for the absence of bruit de soufflet in the early stage of the disease, the lung overlapping it in such a way that the respiratory murmur completely masked every other sound. The aneurismal tumor seemed to consist of three portions, one to the left, which was filled with fluid blood, another lower down, in front of the spine, containing a dense firm coagulum. Dr. Law thought it probable that the disease commenced originally in the right side, and extended afterwards to the left, and that it was this latter portion which had been diagnosed during life. The sac had exercised a slight degree of pressure on the trachea, and on the lung, particularly at the left side. There was no symptom of paralysis. The first symptom was derangement of the sto-

mach and digestive system, and this was followed by the radiating pains and difficulty of deglutition. It was these pains, and the recollection of other similar cases attended by analogous symptoms, which led Dr. Law to suspect the existence of ammonia; the small tumour presented itself posteriorly between the scapula and the spine, it was impossible to determine its nature with accuracy. Dr. Law said that as the preparation had been only a few hours in his possession, he had not been able to examine it as minutely as he wished, and hoped to be able to bring it more fully before the Society at the next meeting. — *Dublin Journal of Medical Science.*

### NEW PREPARATIONS OF IRON.

*Citrate of iron.*—The citrate of iron appears to have been first introduced to the notice of the medical profession by M. Béral, of Paris. The process given by this pharmacien for the preparation of the salt, and which was published in 1831, is as follows:—

Take of crystallized citric acid four ounces. Distilled water four ounces. Moist hydrated peroxide of iron about eight ounces. Weigh the acid and water in a platinum capsule, and apply heat; when the acid is dissolved, and the solution boiling, saturate it with the oxide of iron, adding rather more of the oxide than the acid will dissolve. When cold, filter the solution, and make the quantity sixteen ounces. This solution, spread out on glass, will speedily dry, and separate itself from the glass in thin lamellæ.

The hydrated peroxide of iron may be prepared either from the sulphate or from the sesquioxide of iron. A formula for its preparation from the sulphate is given in the Edinburgh Pharmacopœia. It is prepared from the sesquioxide, by dissolving this oxide in hydrochloric acid, and precipitating with ammonia.

The oxide of iron and citric acid combine in the proportions of forty parts of the oxide to seventy of the crystallized acid. In using the moist hydrated oxide, as the degree of moisture will be subject to variation, the oxide should be added in excess.

The salt thus formed is uncrystallizable; it strongly reddens litmus paper, and has an acid, not unpleasant, taste. It is very slowly soluble in cold water; so much so, indeed, as to have led to the supposition of its being insoluble. It dissolves readily in boiling water.

*Ammonio-citrate of iron.*—If to the acid citrate of iron in solution, prepared according to the foregoing process, ammonia be added, so as to neutralize the excess of acid, a double salt is obtained, which dissolves in cold water much more readily than the citrate,

and which, from its neutrality, may in some cases be preferable to the other.

This neutral salt is frequently sold under the name of *citrate of iron*, and having been ~~introduced~~ introduced to the notice of medical men, under this appellation, without its real constitution being explained, it is the salt generally referred to, where *citrate of iron* is ordered in prescriptions. Much inconvenience frequently arises from this circumstance, the dispenser being at a loss to know whether he should use the salt which the term *citrate of iron* most correctly represents, namely, the ~~acid citrate~~ acid citrate, or that which is more frequently intended by the prescriber, namely, the *ammonio-citrate*; the latter being imperfectly and improperly described by the term *citrate of iron*. It is very desirable that such a nomenclature should be adopted, in the case of these two salts, as would obviate this confusion; and it is hoped that the publication of the formulæ for both preparations may tend to effect this object.

*Lactate of iron.*—The preparation of this salt is effected, according to M. Louradour, by the direct action of a dilute solution of lactic acid on iron filings.

The lactic acid is obtained by the spontaneous fermentation of milk. To eight pints of milk add eight ounces of sugar of milk dissolved in water; leave this mixture, in an open vessel, exposed to the air for several days at a temperature of between 70° and 80°. The liquid being now found very acid, is to be neutralized with bicarbonate of soda; on further exposure this will become again acid, and must be neutralized by the addition of more of the alkali, and the same process repeated until the whole of the sugar of milk has been converted into lactic acid. The liquid is now to be boiled to coagulate the caseum, and the filtered solution carefully evaporated to a syrupy consistence. The product of the evaporation is taken up by alcohol, which dissolves the lactate of soda. Sulphuric acid, added in proper quantity to the alcoholic solution, forms sulphate of soda, which is precipitated, while the lactic acid is retained in solution, nearly pure. It may now be obtained by evaporation of the alcohol.

In a weak solution of this acid in water, iron filings are to be digested at a gentle heat for six or seven hours; after this, boil the liquor, filter, and concentrate the solution, until crystals of the salt are afforded on cooling. These crystals are to be put into a funnel, washed with alcohol by displacement, and dried quickly.

This salt, which is a lactate of the protoxide of iron, is generally met with in the form of a yellowish or greenish white powder. It is but little soluble in water; it reddens

litmus paper, and has a ferruginous taste. When dissolved in water, the iron passes to a higher state of oxidation, and the salt becomes yellow.—*Pharmaceutical Journal*.

### ON SOME PREPARATIONS OF ROSES.

THE combination of the infusion of roses with disulphate of quina, although it has been long in use, is not so eligible a preparation as it might be made, and the tannate of quina, which is formed immediately the mixture is prepared, has long since been objected to, and remarked upon by writers on pharmacy. It is generally stated, that this precipitate is re-dissolved by the addition of a little more sulphuric acid; but this is not correct.

To obviate this objection, I have undertaken a few experiments, and I find that by substituting an equivalent of diluted nitric acid for the diluted sulphuric acid, a clear solution of disulphate of quina is obtained.

Another method consists in depriving the infusion of the tannic acid, which may be done by means of isinglass, in the following manner:—

Take three drachms of rose-leaves, ten ounces of water: infuse cold for six hours.

Take of isinglass one drachm; water, at 110° to 120°, ten ounces. Dissolve.

Having strained the infusion, add the cold solution of isinglass, mixing them thoroughly; the tannate of gelatine is precipitated, and may be separated by filtration, and the requisite quantity of sulphuric acid and sugar should then be added. Cold water is recommended in this infusion, on account of the greater facility with which the precipitate separates; if hot water is employed, a milkiness in the fluid is produced, which passes in that state through the filter, unless it has previously stood twelve hours, or more; in using cold water it is important that the rose buds should be well broken down in a marble mortar, and the infusion should be occasionally stirred.

The infusion thus made dissolves a considerable quantity of disulphate of quina, and the astringent flavour, which is objectionable to some patients, is avoided.

In suggesting this modification of making the infusion of roses, it must be understood that I am not recommending to my brethren a deviation from the Pharmacopœia, but pointing out to the profession a means by which disulphate of quina and the infusion of roses may be elegantly combined.

This infusion is less liable to spoil than that which is made in the ordinary way.

Having proposed a method by which the infusion of roses may be deprived of its

astringent property, it may be well to publish a mode of concentrating this principle in cases where a styptic is desirable: for this purpose a strong tincture is a convenient preparation, and the following formula I have found to answer the purpose.

Rose petals, broken down, five ounces; Proof spirit, made with rose water, one pint. Digest for three days, frequently shaking, and press off. Digest the mass with half a pint of proof spirit for three days, press off, and mix the two liquids to form the tincture for use.

Disulphate of quina may be given with the tincture, and has been prescribed as follows:—

Disulph. Quinæ, gr. i.; Tinct. Rosæ, ℥xx.; Acid. Nit. dilut., ℥x.; Aquæ, ℥iiss.

This forms a clear solution, but if sulphuric acid is substituted for nitric, the precipitate occurs as in the common infusion of roses.

The tincture of roses has been prescribed in cases of hæmorrhage, also as a wash for the mouth, and may prove a useful styptic, mixed with solution of alum; and in cases of hæmoptysis, acetate of lead may be administered with it, if nitric acid be in slight excess.

Tincture of roses occurs in several of the old Pharmacopœias, but the preparation is similar to our infusion, and I am not aware that a formula for a tincture, according to our present acceptation of the term, has been published.

Percolation can be employed both for this preparation and the infusion, the petals being rubbed down with sand; but I have restricted my observations to that plan, which appears to answer very well, and is probably the most eligible in practice.—*Mr. Squire, in Pharmaceutical Journal*.

### MEDICINAL PROPERTIES OF SOLANUM TUBEROSUM.

FROM the leaves gathered at the proper period, and subjected to careful preparation, the extract, which I have the honour of offering to your notice, is procured, possessing narcotic powers of a very high degree.

In the sixth volume of the Transactions of the College of Physicians, is a paper, by Dr. Latham, on the Medicinal Properties of Solanum Tuberosum: it was read in the year 1818, since which time I have every reason to believe the extract has entirely fallen into disuse. Dr. Latham states that "an accident which he witnessed, occurring to an animal, ought to have induced him sooner to have made a trial of its narcotic powers upon the human body, and the effects pro-

duced in the following cases will, perhaps, entitle it to a rank of no mean estimation in the catalogue of medicines." The doctor then furnishes us with the detail of seven cases, in most of which the powers of the extract were particularly marked.

As a medicine the extractum solani tuberosi will rank between belladonna and conium: it has a decided tendency to produce relaxation of the bowels, and, therefore, will, in many instances, supply the place of opium. In a large dose it produces all the effects of narcotic poisons—headache, vertigo, stupor, &c.; but in moderate ones it seems to me to possess powers far more certain than either hyoscyamus or conium: it is particularly serviceable in chronic rheumatism, painful affections of the stomach and uterus.

Should experience confirm the virtues which I believe reside in this preparation, a great advantage will accrue from the large and certain supply always to be obtained: this is not the case with the other narcotic plants, hyoscyamus and conium, which, in some seasons, can with difficulty be obtained in sufficient quantities. The samples of extract and preserved juice upon the table, were kindly prepared for me by a member of your Society, Mr. Edwards, of Great Russell Street; they will be found, upon inspection, to possess not only the odour, but the taste, of the class of plants to which the solanum tuberosum belongs. I am aware that much time is required to ascertain the merits of any new medicine, and that nothing but the most careful and repeated observation can entitle it to rank among the articles of the materia medica; yet, from the trials I have made with the solanum tuberosum, I am induced to place considerable reliance on its powers, and have, therefore, much pleasure in offering it to the notice of this Society.

The dose of the extract is from one to three grains, three times a day.—*Mr. Dyer, in Pharmaceutical Journal.*

#### DR. WATSON'S LECTURES.

THE omission of two weeks in the publication of Dr. Watson's lectures was to suit his convenience. We have resumed them this week, and purpose to complete the course in the current volume.

#### ROYAL COLLEGE OF SURGEONS.

##### LIST OF GENTLEMEN ADMITTED MEMBERS.

*Friday, May 20, 1842.*

E. N. Sison.—J. Southern.—J. Douglas.—W. G. Eaststaff.—N. Montefiore.—M. Hare.—C. Gibson.—A. B. Steele.—H. T. Berry.—E. Pye.—P. Brotherston.—A. Taylor.—C. Robinson.—J. Rowlands.

#### MEDICAL ASSOCIATION AT BRENTFORD.

*(From a Correspondent.)*

WE are happy to hear that the medical practitioners of Brentford and its vicinity have resolved to form themselves into an association for the purposes of friendly intercourse and mutual advantage, to be called the "Brentford Medical Association." It will include all practitioners resident in the several parishes comprising the Brentford Union, who may be willing to join it, and be likewise open to those of the neighbouring districts.

LECTURES  
ON THE  
PRINCIPLES AND PRACTICE OF  
PHYSIC,

*Delivered at King's College, London,*

BY DR. WATSON.

*Treatment of the various species of jaundice. Diseases of the gall-bladder; of the spleen; of the pancreas. Diseases of the kidneys. Nephritis and nephralgia. Phenomena constituting a "fit of the gravel." Different kinds of gravel. Diseased states of the urine. Description and remedies of the lithic, phosphatic, and oxalic diatheses.*

IN the last lecture, after describing the symptoms, and causes, and treatment of acute and chronic inflammation of the liver, and after pointing out various other forms of chronic disease to which that organ is obnoxious, I spoke of *jaundice*. I offered you some comments upon its phenomena; and I indicated several different internal conditions upon which it may, in different cases, depend: and the lecture was closed with some brief hints respecting the *prognosis* of *icterus*. I have yet to consider the plans of treatment best adapted to the several varieties of the complaint.

Some kinds of jaundice are obviously and absolutely irremediable. From others the patients recover whatever treatment may be adopted, or without any treatment at all. Hence, as is customary in such circumstances, remedies the most worthless and absurd are extolled for their efficacy against jaundice. The patient gets well, and the drug last tried is held to have cured him. *Post hoc, ergo propter hoc*, is an argument more often applied I believe to the variations of disease, than to any other class of events.

757.—xxx.

In that species of *icterus* which occurs, sometimes, in connexion with acute or chronic inflammation of the liver, the treatment must be such as I yesterday recommended for acute and chronic hepatitis. Mercury forms an essential part of that treatment; and, unless the disease yielded sooner, I should urge the remedy until its effect upon the gums, and, therefore, its presence in the circulating blood, was apparent.

But to the *icterus calculosus*, mercury is not so well adapted. What we want is, not a more plentiful or a more healthful secretion of bile, but to get rid of the mechanical impediment to its excretion; or, at any rate, if that cannot be accomplished, to ease the acute sufferings of the patient. If fever attends the passage of a gall-stone, or if the epigastric pain should become epigastric tenderness, leeches may be applied, or a vein may be opened. The abstraction of blood may prevent any thickening of the distended gall-ducts; or it may perhaps relax their spasmodic closure around the calculus. But, in general, blood-letting is not of service nor requisite in this variety of jaundice. Our great resource for relieving the pain, and for loosening the presumed spasm, is opium, given in full doses: and I can add but little, with any advantage, to the directions laid down, on this head, by Dr. Heberden. "This pain (says he) can only be assuaged by giving and repeating opium and its preparations, as often as the continuance of the pain requires them; and because this pain is very apt to return, the patient should always be advised to keep by him, as long as the distemper lasts, pills of pure opium, each weighing one grain—or what is equivalent to them—that no time may be lost in quieting a sensation which is so difficult to endure. One of these pills may be taken as soon as the pain comes on, and it may be repeated once or twice in the course of two hours, if the pain require it; and I have often found it both safe and necessary to give much more."

2 B

This plan, of giving opium in the form of *pills*, is the more judicious, because, from their small bulk, they are more likely to be retained than draughts would be. Sometimes the stomach is so irritable as to reject even a pill. I would add, therefore, to Dr. Heberden's recommendations, that of throwing an opiate injection into the rectum; half a drachm or a drachm of laudanum, mixed with a small quantity of warm gruel. Another very useful expedient is the warm bath. If this cannot be readily procured, hot fomentations to the epigastrium, the mustard poultice, the turpentine stupe, are valuable substitutes for it. Dr. Prout states that he has seen more immediate alleviation afforded by large draughts of hot water, containing the carbonate of soda in solution (one or two drachms to a pint), than by any other means. "The alkali counteracts the distressing symptoms produced by the acidity of the stomach; while the hot water acts like a fomentation to the seat of the pain. The first portions of water are commonly rejected almost immediately; but others may be repeatedly taken; and after some time it will usually be found that the pain becomes less, and the water is retained. Another advantage of this plan of treatment is, that the water abates the severity of the retching, which is usually most severe and dangerous where there is nothing present upon which the stomach can react. This plan does not supersede the use of opium, which may be given in any way deemed most desirable; and in some instances a few drops of laudanum may be advantageously conjoined with the alkaline solution, after it has been once or twice rejected." The pain having been quelled, the bowels should be swept out by a brisk purgative.

When jaundice appears to have been suddenly engendered, by moral causes, the rationale of its production is obscure; and the treatment has a corresponding uncertainty. The bile, retained or readmitted into the blood, is supposed to operate, as a poison, upon the nervous system. But the mental state which precedes and seems to occasion the jaundice, may possibly be itself the cause of the nervous symptoms that follow. In other forms of the malady patients remain intensely yellow, often for a long time together, without becoming comatose, delirious, or convulsed. Not that this is conclusive. We know that a given poison may influence different persons very differently. The same dose of opium that will put one man to sleep, will stimulate a second to madness, and will have no sensible effect upon a third. In the very complaint before us, one patient is tormented with a universal itching, which we attribute to bile in his blood; and ten others remain free from that disagreeable feeling. If we were sure that the bile was

the material cause of all the cerebral symptoms, we might hope to draw some of the poison off by blood-letting: but we are not sure of this; and reasoning upon the matter helps us not much towards the cure. The lesson which experience has furnished amounts to no more than this: that active purging is sometimes followed by evident amendment, and ultimate recovery. I would bleed also, if the *pulse* warranted venesection, but not otherwise. In all the varieties of what, from its intensity and rapid accession, I may call acute jaundice, purging is strongly indicated: and we sometimes succeed in rectifying the whole morbid condition by thus applying a sudden *wrench* (so to speak) to the biliary organs; by giving, for instance, half a scruple or a scruple of calomel, and, a few hours afterwards, half an ounce of castor oil, with half an ounce of spirit of turpentine.

When *green jaundice* arises from hepatic disease, we can only palliate. Mild laxative and anodynes comprise all that such a state admits of. For the *icterus gravidarum*, delivery is the natural cure: it may sometimes be removed by the careful employment of aperients.

The *gall-bladder* has its own diseases, which I do not stop to investigate, for they seldom become the objects of specific treatment. Sometimes it is found shrivelled up, and nearly empty: sometimes enormously distended; sometimes ruptured. Of these conditions, the distension of the gall-bladder is the only one that we can ever expect to recognize in the living body. The bag then projects beyond the edge of the liver, and is palpable externally, forming an elastic tumor in the right side. Authors lay down marks for distinguishing a distended gall-bladder from abscess of the liver, and from an hydatid cyst; but they are not much to be trusted to; nor is the precise diagnosis of any great moment. The practical rule seems to be that, when the swelling is adherent to the parietes of the abdomen, we may puncture it, whatever is its nature: but under no other circumstances.

I have already, incidentally, described most of the morbid states of the *spleen* which are susceptible of relief from medicine: especially the enlargement of that body constituting the *ague-cake* of the fens, and occurring in connexion with intermittent fever; and that other kind of enlargement which sometimes goes along with hematemesis and melœna. The spleen is liable to tubercles also; to deposits of other specific tumors, and of bone; and to softening of its substance.

The best remedy for the *ague-cake* is the remedy for intermittent fever, *quina*. Purgatives also have the effect of reducing hypertrophy of that curious organ. One can-

tion, laid down by Dr. Abercromby, is that in splenic disease, mercury should be sedulously avoided, or rather such an employment of mercury as would risk tenderness of the gums. Dr. Williams, of St. Thomas's Hospital, states in a recent publication that he has made many trials of the *bromide of potassium* as a remedy in various disorders; but that he has satisfied himself of its utility only in cases of diseased spleen. Of this I know nothing.

Again, it may seem a slight to the *pancreas* to pass it over without noticing the diseases to which it is subject. But really those diseases appear to be but few; and they do not signify their existence by any plain or intelligible signs. I have, eight or nine times perhaps in my life, met with carcinomatous deposits in the pancreas. In every instance the head of the gland, that extremity which lies next to the bowel, has been the exclusive or the principal seat of the disease. I have known this change in the pancreas cause jaundice, by obstructing the bile ducts; and I have known it produce enormous and slowly fatal distension of the stomach by compressing the duodenum, and so preventing the free passage of the aliment through that gut. As to remedies for pancreatic diseases or disorders, I do not know of any.

Diseases of the *kidneys*—and disorders of their function—and alterations in the fluid they secrete—require more consideration. And I proceed at once, *in medias res*, to the subject of their *inflammation*; to *nephritis*: and it will be practically convenient to take *nephralgia*, or pain of the kidney, into the account at the same time. Nephralgia is commonly, but not always, produced by the transit of a urinary calculus from the pelvis of the kidney, through the ureter, towards the bladder. This constitutes what is called, in common parlance, a *fit of the gravel*. The symptoms are these:—pain, sometimes dull, but more frequently very severe, in the loins, usually on one side, and descending often along the track of the ureter of the same side; numbness of the corresponding thigh; in the male, retraction, and perhaps pain, of the testicle; a frequent desire to make water, which is generally high coloured; nausea and vomiting.

If to these symptoms there be added pyrexia, we learn the important fact that inflammation is present: we have the symptoms of *acute nephritis*. The passage of gravel from the kidney sometimes does, and sometimes does not, provoke inflammation of the gland. Nephritis is very seldom idiopathic. It may sometimes arise under the influence of cold: more frequently it is excited by calculous matter lodged in the

kidney; by a blow or fall upon the loins; by the internal administration of cantharides, or of turpentine. It is to the presence of fever that we look, to establish the inflammatory character of the renal affection.

Nephralgic pains require to be distinguished on the one hand from rheumatic, and on the other from colic pains. In lumbago there is pain in the back, and it may or may not be attended with fever; but the pain usually affects both sides, and is aggravated by such movements of the body as call the muscles of the loins into action, particularly by stooping. It originates, frequently, in some strain or effort, of which the patient is made painfully conscious at the time. It is seldom accompanied by any notable trouble of the urinary functions. When rheumatic pain extends from the back into the thigh, it mostly follows the course of the great sciatic nerve, and is felt down the outer part of the limb; whereas the pain that accompanies nephritis or nephralgia shoots rather along the track of the anterior crural nerve. Lastly, lumbar pain, depending upon rheumatism, is not attended with nausea and vomiting.

The pain of colic is often associated with sickness and retching: and it may occupy those parts of the abdomen which correspond to the place of the ureters. The urinary functions are undisturbed; and this is a capital point of distinction. The numbness of the thigh, and drawing up of the testicle, are sufficiently characteristic, when they happen; but they are frequently altogether absent.

Some years ago I was sent for by an exceedingly intelligent surgeon, who had been one of the house-surgeons at the Middlesex Hospital. I found him in bed. He told me he had a pain in the abdomen. It had begun in the morning in the situation of the right kidney, and soon extended round to the right side of the abdomen and the groin. Two days before, he had experienced a similar attack of pain in the renal region, stretching round into the hypogastrium. When I saw him he described the pain as lying more round the umbilicus than elsewhere; and he expressed a strong persuasion, from the feelings which attended it, that it would be removed by free action of the bowels. But he felt nausea; and had vomited some medicine which he had taken. He had no fever, no retraction of the testicle or numbness of the thigh, and the pain was not increased by pressure. Neither had there been any marked irritation of the bladder. He said, indeed, when I questioned him on that point, that he *thought* he had made water *rather* more frequently than usual the day before. I mention this case to show you the occasional obscurity of the symptoms. Here a well-instructed medical

man believed that nephralgia, existing in his own person, was colic. To my judgment, however, it seemed most probable that a small calculus had been passing from his kidney towards and perhaps into his bladder. I may as well tell you the event of the case, which interested me a good deal; for it exhibits the train of symptoms that are apt to ensue after nephritic attacks: although in this instance they were but slightly pronounced. His bowels were well acted on by a purgative, and the next day he was free from pain, and apparently well.

Two days after this, he had more frequent calls to pass urine than were usual with him, and having done so on one occasion, he presently felt the want again, and then passed a little blood. The urine had been of a clear amber colour throughout. At the expiration of two or three days more he called upon me to say that after making water he had perceived in the vessel a small crystallized mass, which he took out, supposing it to be (what it very much resembled) a small fragment of sugar candy. In fact he had been eating sugar candy, and thought some portions of it had fallen down between his waistcoat and shirt, and afterwards into the chamber-pot. He had the curiosity, he said (some misgiving he must have had too, for I had told him my own opinion of the nature of his attack), to put a small crystal from this fragment into his mouth; and as it neither tasted sweet nor dissolved, he suspected it might be a urinary concretion, and brought it to me. And sure enough it was so; a piece of very pure oxalate of lime, which he had been fortunate enough thus to get rid of. It was a quarter of an inch in length, and less than one-eighth of an inch broad, consisting of an aggregation of small crystals. It was exactly similar in appearance and colour to a piece of brown sugar-candy of the same size. It would pass, longways, into a large crow-quill.

That it was oxalate of lime was proved in this manner. A little separate crystal was heated to redness on a piece of platinum foil, by means of a spirit lamp and blow-pipe. By these means the oxalic acid was destroyed, and quick-lime left. This residue, moistened, and pressed into a powder on a piece of turmeric paper, gave the characteristic brown colour.

You see, then, that a nephritic affection may be mistaken for an attack of colic. In reference to practice, it would indeed be a mistake of no great importance, since the remedies that are proper in the one case are generally proper, or not improper, in the other. If the pain be attended with fever, antiphlogistic measures are alike indicated in each of the two diseases.

The numbness of the thigh, and the drawing up of the testicle, are analogous

phenomena to the pain which affects the shoulder in hepatic disorders. Irritation of one extremity of a nerve, situated internally, and belonging to an organ which is not endowed with a high degree of sensibility, causes sympathetic sensations in the sentient extremities of other branches of the same nerve, or of communicating nerves.

And this sympathetic affection of distant parts is sometimes attended (as I formerly observed) not merely with pain, but with some degree of inflammation also. The testicle occasionally swells, and becomes tender, during a nephritic attack. On the other hand, as the nerves which communicate with those of the testicle or thigh may or may not be implicated in the renal disorder, so we see how it happens that these curious symptoms, so instructive when they do occur, may frequently be wanting; as they were in the example I just now detailed to you.

When the symptoms I specified in the outset are attended with fever, we conclude that we have to deal with nephritis; and when inflammation of the kidney, however produced, lasts for a certain period, without abatement, *suppuration* is to be dreaded. Such suppuration is marked, sometimes, by the supervention of rigors, by throbbing perhaps, and it may be by a remission of the pain: but I believe it may take place without throwing out any such signals. Nay, I think it probable that inflammation, confined to the parenchymatous substance of the kidney, may arise, and run through all its stages, without denoting its presence or progress by any noticeable local signs; and that the sharp and peculiar symptoms ascribed by authors to acute nephritis manifest themselves only when the investing membrane of the gland, or its pelvis and excretory tubes, are involved in the inflammatory process. However this may be, suppuration leads to ulceration, to the formation of renal fistulæ, to the establishment of a purulent discharge, and hectic fever; and finally, in most cases, to a fatal event; whether the inflammation was at first idiopathic, or dependent on a calculus.

I may illustrate these remarks, by stating the heads of a case which has occurred to me since this course of lectures began. I admitted Caroline Barnard, a married woman, forty years old, into the hospital, on the 18th of October. Among other things she complained of pain in the situation of the right kidney. She had been ill six weeks, and at the commencement of her illness her urine had been very turbid, as indeed it still was; and she had experienced much pain and difficulty in passing it, and after it had passed. From that time she had frequent nausea and retching, and occasional numbness of the right thigh. She had been losing flesh fast; and her pulse was frequent. There was some tenderness discoverable in

the right renal region; and after a time a manifest fulness there, and hardness; and at length œdema of the integuments and *extreme* tenderness. She suffered also well-marked hectic fever, and had severe and repeated rigors. On the 4th of November, after a careful examination of the right loin, we satisfied ourselves of the presence of matter. I got Mr. Arnott, therefore, to see her, and to put a lancet into the abscess; and a large quantity of faint-smelling pus came out. She was greatly relieved by the operation; and a purulent discharge, mixed with shreds of cellular membrane, came away in abundance for some days: but in time the discharge ceased, the swelling subsided, and the opening healed. We began to hope that it had been merely an abscess in the *neighbourhood* of the kidney, irritating it and affecting its functions. But in three weeks after the abscess was punctured, the swelling was found to have recurred; and she again began to suffer much. The tumor was again opened, and pus of a more offensive character than before evacuated. In the early part of December she sunk.

We found the right kidney small, collapsed, and hollow; in some parts a mere flabby bag. On its posterior surface there was an opening, which formed a communication between the interior of the kidney and the abscess in the cellular tissue, which had pointed externally. The pelvis of the kidney was much dilated; and the substance of the gland destroyed to a considerable extent, by suppuration and ulceration. The ureter, where it left the pelvis of the kidney, was found to be impervious.

The other kidney was much enlarged; but of quite healthy and sound structure. That kind of compensation had occurred which I formerly mentioned as not unusual when, of double organs, one has been rendered incapable of its natural functions, and the other takes up its duty, and performs a twofold amount of work. The organ of which the function is thus increased, becomes hypertrophied. This woman did not die because there was not urine enough secreted; but she sunk under the wasting purulent drain, the irritation and pain she suffered, and the protracted hectic fever. In this instance the inflammation and suppuration occurred independently of the formation of calculous matter.

Sometimes the pus finds its way out of the body through the natural passages, and appears in the urine. This woman's urine was thought, by some of the pupils, to contain pus. It was quite thick, and of a yellowish colour. But heat rendered it transparent. You must not judge by a cursory look at the water. The effect of heat proved that the yellow material was not pus; the

impervious condition of the ureter showed afterwards that it could not have been.

When calculi exist in the kidney, they often give tokens of their presence there, by causing *bloody* urine. But bloody urine may proceed from various causes; and in conformity with my usual custom, I shall by and by offer you some general remarks on hæmaturia, as one of the hæmorrhages.

I showed you, at our last meeting, that gall-stones might inhabit the gall-bladder in considerable numbers, and be quite harmless, unless they attempted to escape from their prison, through the very narrow channel of egress from it; and I intimated that the same observation was often applicable to urinary concretions. Renal calculi do indeed, in many cases, produce abiding uneasiness, or frequently recurring pain, in the situation of the affected kidney, bloody urine, and gastric disturbance; especially when the concretions are shaken or displaced by sudden jolts or jarring movements of the body; or when the system is deranged by intemperate habits. But in many other instances these calculi cause no pain or annoyance, so long as they remain in the kidney: although they inflict horrible suffering, in general, while, for the first time, they are forcing their way along the narrow ureter. A concretion cannot be formed in a moment; yet the attack of pain often comes on in a moment, without any previous warning. After a while it remits, perhaps as suddenly; the calculus having passed (it may be presumed) from the ureter into the bladder; and then indications, more or less palpable, usually begin to declare themselves of its presence in that reservoir. Moreover, it is not uncommon to find calculi in the kidney after death, of the existence of which there had been no symptom manifested during life.

The *treatment* of nephritis—or of the nephralgia calculosa, when accompanied by fever, or occurring in young, strong, and plethoric persons—is just such as would be proper in cases of severe colic, or enteritis: and therefore it is that any mistake between these disorders at the outset is not of so much practical consequence. The objects of treatment are, to arrest the inflammatory process; to quiet existing irritation; and to obviate any fresh causes of irritation. Venesection, therefore, in proportion to the strength of the patient and the violence of the symptoms, will sometimes be proper: and it will always be advisable to take away blood freely from the neighbourhood of the suffering part by cupping. Warm fomentations; the warm bath; the injection of warm water into the bowel; these are all expedients of which practical men acknowledge the value. The warm enemata not only clear out from the large intestines any irritating matters they

might contain, but, from the proximity of the colon to the kidney, they perhaps have the effect of an internal fomentation. It is desirable also to get the bowels well acted upon by purgative medicines as soon as possible: the relief that follows free alvine discharges is often very marked. There is sometimes a difficulty, from the irritability of the stomach, in administering purgatives by the mouth. Calomel, however, will often be retained, when other substances are rejected. It is generally considered of importance to give those purgatives only which are not likely, by being absorbed into the blood, to irritate the urinary passages. On this account the *saline* purgatives are to be avoided. Nothing is so good as castor oil, if the stomach will bear it; or infusion of senna with manna may be used; or, if the stomach be very queasy, *pills*, composed of cathartic extract, and calomel.

When there is no fever, *i. e.* when the case is one of nephralgia, and a calculus is passing, after the intestinal canal has been cleared by a purgative, it will be necessary to give opium in full doses to allay the pain: and it may either be administered in the form of pill through the stomach; or introduced into the rectum.

When a person suffers what is called a fit of the gravel, the pain, I say, is at length very suddenly relieved, in general, in consequence of the calculus having emerged from the ureter and entered the bladder. We judge that this has taken place, first, by the cessation of the pain; and secondly, by the supervention, sooner or later, of the symptoms indicative of stone in the bladder: *viz.* a more than usually frequent inclination to make water; pain, referred to the extremity of the urethra, especially just after passing urine; and a stoppage and renewal of the stream of water during its exit.

The time which a calculus takes in travelling from the kidney to the bladder varies a good deal. The painful journey may be over in a few hours; or it may last two or three days. More rarely the symptoms continue, with irregular intervals of comparative quiet, for weeks. And sometimes, notwithstanding the peculiar pain, which amounts to torment, all morbid symptoms cease, and yet no calculus has passed, apparently, into the bladder: none, *i. e.* of the symptoms of stone ensue; no calculus is voided by the urethra; and none found in the bladder when the patient at length dies.

What is the explanation of these circumstances? Why, as calculi have been discovered in such cases in the *kidney*, it has been supposed that a concretion may get into the very beginning of the ureter, where it is a little larger than elsewhere, and give rise to the peculiar symptoms, yet never pass

fairly into that narrow tube; but at length fall back again into the pelvis of the kidney: when the symptoms cease.

But the same symptoms undoubtedly occur, occasionally, when there is no calculus at all. Sir B. Brodie has referred to this form of complaint. In people who live intemperate and luxurious lives, pain is apt to seize upon one renal region, and to extend round and downwards into the groin; and these symptoms will be followed by frequent, difficult, and painful micturition, the urine being unusually acid, high-coloured, and sometimes turbid. The whole irritation appears to be produced by this unhealthy urine: at least the complaint vanishes after cupping the loins, purging, the warm bath, and two or three full doses of colchicum given at short intervals.

Sometimes the little stone becomes immovably wedged in the canal of the ureter. If it completely shuts the tube, the urine accumulates behind it, and that portion of the ureter dilates. The obstruction usually proves fatal, by its influence upon the functions of the kidney, and thereby upon the whole economy. But if the urine finds a passage by the side of the impacted concretion, this danger is averted, or postponed.

When we have reason to believe, from the nature and course of the symptoms, that a calculus has come down from the kidney, and lodged in the bladder, then it becomes an object of deep interest to the practitioner, and of fearful importance to the patient, to try all means to bring about its expulsion before it grows too large to be voided. For grow it almost surely will, by the continual accretion of earthy matter upon its surface, if it remains long in the bladder. We know that it *may*, at first, be voided, provided the urethra be in a healthy and natural state: that whatever has passed through the ureter, may pass through the urethra also.

The objects to be kept in view are these: first, to procure a plentiful secretion of bland urine, wherewith the bladder may become filled; secondly, by lulling the sensibility of the parts concerned, to prevent or lessen that spasmodic constrictive effort of the sphincter of the bladder, which the presence of the calculus is apt to provoke; and, thirdly, to ascertain that the channel of the urethra is open and unimpeded.

To effect the first of these purposes, the patient should be instructed to drink freely of diluent liquors; such as barley-water, or linseed-tea, in which may be mixed a small quantity of the sweet spirits of nitre. To fulfil the second, he should take a full dose of opium at bed-time. By these means the pain and irritation which may have been produced by the calculus, will be soothed; and the bladder will gradually fill. He should

then make water, having first placed himself in such a position that the outlet of the bladder shall be at the lowest part of that receptacle. He may stand up, and lean forwards; or it may be well to make water while kneeling, in a warm bath. If these expedients are not presently successful, the urethra may be cautiously expanded, and habituated to the contact of a solid body, by the daily introduction of a full-sized bougie. Sometimes the calculus will follow the bougie, as it is withdrawn, through the urethra. In this way the patient will have a fair chance of getting rid of the stone. In this way a very near friend of my own, a physician now practising in this town, did expel a formidable, though not very large, piece of rough oxalate of lime several weeks after its entrance into the bladder. Out it came, at last, with a smart clink, which was music to his ear, against the chamber-pot. A gentleman was not long since sent up to me from Kent, by a former pupil of this College, with the following history. About a month before he had been suddenly attacked with acute pain in the loins, extending forwards into the left flank, and pelvis, with nausea and vomiting. For nearly ten days these symptoms continued to occur at intervals; then they ceased; and then he began to be troubled by a frequent and very urgent inclination to make water, and by pain after voiding it, just above the arch of the pubes. I gave him directions, in accordance with the plan just now mentioned; and wished him to allow some surgeon to explore the contents of his bladder. To this he would not, as yet, he said, consent. I saw him on the 2d of August. He returned into Kent the next day. On the 5th, while taking a walk, he was seized with a most imperative desire to make water, but found that he could part with none. Concluding that a calculus had entered, and stopped up the urethra, he was proceeding homewards, but was soon constrained again to try to empty his bladder: and then he had the satisfaction of feeling, and seeing, a stone fly out with great force: but, as he had turned towards a hedge, he could not find it. From that moment he was quite easy.

When a calculus of a certain size has once traversed the tubes that lead respectively to and from the bladder, others sometimes follow it with more ease. I shew you here a large concretion which was passed, or pined if you will, by a patient of mine without his knowing it. He is subject to epilepsy, which is probably eccentric, and excited by renal disease. He is closely and anxiously watched by his wife. One day last year she noticed that the urine he had just voided was slightly tinged with blood:

and she then found this oblong stone, which is composed of lithic acid, in the vessel.

If the renal calculus, after it has reached the bladder, cannot be got rid of by the expedients I have been recommending, the question arises whether medicine can do any farther good, or whether the patient is to be delivered over to the surgeons.

Most of these small concretions admit of being mechanically crushed into smaller fragments, which are then readily washed out by the stream of urine. Larger stones are extracted entire, through incisions of the bladder. Yet there are many cases in which, for various reasons, surgery declines to attempt the removal of vesical calculi. Medicine still offers to these unfortunate patients the means of mitigating, at least, their sufferings. But it often can do more than this. It is very important for you to know that judicious medical treatment may retard or prevent, and that injudicious medical treatment may promote and hasten the enlargement of such calculi. Let us briefly consider the principles by which our judgment and our practice, in this serious matter, must be guided.

I have described a fit of the *gravel*. We say that a patient has the gravel when he passes concrete matter with his urine, whether in the form of powder, of grit or sand, or of more massive calculi. We do not apply that term to the cases in which the urine is clear when recently voided, and warm; but throws down an earthy sediment as it cools: which sediment redissolves if the urine be again artificially heated. Now besides the different forms which the gravel assumes, of powder, sand, and little stones, there are (as you may have guessed from certain terms that I have been obliged to employ) several *kinds* of gravel; differing, I mean, in their chemical composition. The main signs—the pain, the sickness, the affection of the testicle, the subsequent bladder symptoms—are much the same, whatever be the nature of the solid matter that descends from the kidney, and lingers in the bladder. But other circumstances differ widely. The qualities of the water previously to the formation, and to the discharge of the sabulous matter; the state of the system at large. And it is quite impossible to treat cases of calculus in the kidney, or of stone in the bladder, with propriety, or safety, without constant reference to the condition of the urine. The morbid states of that secretion are of the greatest interest. I cannot undertake to enter upon that subject in much detail. Yet some outline of it I must attempt, especially where it touches upon points of practice.

You know, probably, that the urine voided by a person in health always exhibits

*acid properties*, always turns litmus paper red. Not that healthy urine contains a free acid; but only (according to Dr. Prout, who is the great authority in these things), that certain of the alkaline and earthy bases are not exactly neutralized, but exist in the state of supersalts. The pure lithic acid is nearly insoluble; but the lithate of ammonia is very readily soluble: and it is this which reddens the vegetable blues. Now, whether out of the body, or within it, the lithate of ammonia will, of course, be decomposed, if any acid be present in the urine, for which ammonia has a stronger affinity than it has for the lithic acid: and the latter will be thrown down, in the form of a red sand: little crystals, in point of fact, they are, very much like, in shape, size, and colour, to particles of Cayenne pepper. I shew you some collected by one of my out-patients at the hospital. He must have passed a peck of it while under my observation: and I am sorry (having lately lost sight of him) that I did not procure a large quantity for the museum.

Now this lithic acid, or red sand, or gravel, is liable to form in the kidney, if not in the bladder, and to concrete into calculi; and the calculi once formed, or, indeed, any solid substance, will constitute a nucleus upon and around which a farther and repeated incrustation of a similar nature is almost sure to take place. You will at once perceive the importance of doing nothing to aggravate this disposition to deposit lithic acid; but of trying to prevent, or stop it. If there be symptoms of stone in the kidney, or in the bladder, and we have reason to believe that it consists of lithic acid, there are medicines which would tend to render matters worse, and there are others of which the effect would be to correct the lithic acid *diathesis* as it is called. But how are we to know whether the presumed calculus be of that kind or not? or, rather, how are we to know that the lithic diathesis exists? Why, we learn that it exists by noticing the habitual qualities of the urine, and the habitual state of the patient's general health.

In the urine of persons who have the lithic diathesis, you will find that there are frequent deposits, after it has become cool, of reddish sediments, looking like brickdust, and, therefore, called *lateritious*. These sediments consist chiefly of the lithate of ammonia, tinged with certain colouring matters in the urine. Sometimes pure lithic acid appears, in the shape of fine sand, or in larger crystals. The urine itself is bright, of a dark coppery colour, like brown sherry. It is more acid than the urine of health, and gives to litmus paper a deeper shade of red. It is apt, too, to fall below the average quantity.

The presence of this diathesis is likewise accompanied, and so far denoted, by a tendency to feverish and inflammatory complaints. The patients are troubled with acidity of stomach, and heartburn; many of them are subject to gout or rheumatism. They are mostly also indolent and luxurious, or intemperate in their mode of life. Adults are peculiarly obnoxious to this condition of the system after the age of forty. But children, up to the period of puberty, are very liable to have lithic acid gravel.

Whenever a paroxysm of nephritic pain befalls a person whose time of life, the characters of whose health, and the qualities of whose urine, are such as I have been describing, you may conclude that the concretion which has occasioned the symptoms is of the lithic acid kind: and you may expect that such attacks will recur; for it is observed of these lithic acid renal calculi, that they are generally numerous in the same individual.

Now the formation of lithic acid may be controlled by the exhibition of alkaline remedies. You will find that free livers use alkalies to neutralize the excess of acid which results from their intemperate habits; the bicarbonates of soda, or potass. They do this, without any reference to the appearance of their urine, to prevent or appease the uneasy feelings produced by a debauch. But it is of importance to be aware that one of these salts is preferable for the purpose of obviating the lithic acid diathesis to the other. Soda will sometimes combine with the lithic acid, and form an insoluble salt, as hard, and as pernicious, when deposited around a nucleus, as the lithic acid itself. With potass there is no such danger. If it should combine with the lithic acid, the resulting salt is perfectly soluble, and will pass away dissolved, in the urine. Magnesia is also a good medicine in such cases; but it has this disadvantage, as I shewed you indeed before, that when taken habitually, it is apt to cause *intestinal* concretions: and these may be as dangerous as the urinary ones. One of the best modes of giving the bicarbonate of potass is in the common saline draught. The stomach has the power, apparently, of destroying the *vegetable acids*, and the remedial properties of the bicarbonate become thus equally certain with those of the pure alkali; and it is much less likely to derange or disagree with the stomach. Of course the mode of living ought to be changed when the lithic diathesis prevails; the patients should dine moderately and plainly, eating of one dish, and avoiding indigestible substances, and fermented liquors. But, as I mentioned in a former lecture, they will not, if they can help it, give up their accustomed indulgences: and they attempt, and we attempt, but the attempt is often made

in vain, to remedy disorders, which might with ease and certainty have been prevented.

You must take care not to give these alkaline remedies too long; nor in too great quantity. You must not push them to such an extent as entirely to destroy the acidity of the urine: for if you do, your patient is exposed to the same danger as before, but from an opposite cause. A *white sand* or gravel will be apt to form in the alkaline or neutral urine: and this will collect itself, by the force of aggregation, around any existing calculus, or foreign substance. The white deposits consist mainly of the triple phosphate of ammonia and magnesia; and if you examine collections of urinary calculi, you will find that they are sometimes made up of concentric layers; and one layer may be composed of lithic acid, and the next of the triple phosphates; and so on, as the condition of the urine has alternated. You must test the urine therefore, and see that it still reddens litmus, though perhaps faintly. The saline draught has always a tendency to make the urine alkaline; and thus it is, probably, that it proves of use in febrile disorders: but it is an absolute poison to those whose urine is already alkaline. Colchicum has a similar tendency to diminish the acid reaction of the urine. So has mercury. And I may tell you—speaking generally of morbid states of the urine—that it is much more easy to correct too great acidity than to rectify the opposite condition. We can almost always make acid urine neutral or alkaline: but to render alkaline urine acid is often beyond our power.

You will have observed, from what I have already said, that there is a morbid condition of the system, the opposite of that in which the lithic diathesis prevails. The phosphatic diathesis, namely; in which there is a readiness to deposit *white gravel*; composed of minute shining crystals of a triple salt, the phosphate of ammonia and magnesia. The way in which this is formed, according to Dr. Prout, is as follows. Healthy urine contains the phosphate of magnesia, which is very soluble; and, therefore, is dissolved in that fluid. But, under certain circumstances, the urea of the urine becomes decomposed in the kidneys, and ammonia is extricated, which combines with the phosphate of magnesia, and forms an *insoluble* triple salt. Sometimes with the triple phosphate just mentioned, there is also an admixture of phosphate of lime.

It is a fact of vast practical importance, that the tendency to the formation of the phosphates goes along with a debilitated condition of the system. Persons who have been rendered weak and feeble by over much toil, by mental anxiety, by insufficient nourishment, are very apt to pass water that is

alkalescent or but faintly acid, and to exhibit the tokens, in their urine, of the phosphatic diathesis. They are, for the most part, cachectic, sallow, languid, spiritless. The urine itself is pale, copious, slightly turbid or opaline, of a low specific gravity, and it does not smell like healthy urine: sometimes it has somewhat the faint odour of weak broth. It is occasionally alkalescent when voided; never more than slightly acid. As the urine cools, the white sand is thrown down; and in many cases a sort of film is formed upon the surface of the water, exhibiting, as you see it in different lights, all the colours of the rainbow: an iridescent pellicle. This has been found to consist of the triple phosphate. If you skim the pellicle off, by placing a bit of paper under it, and then suffer the paper to dry, you may distinctly see the little crystals. Urine of this kind speedily grows putrid and highly offensive. Sometimes it has a strong ammoniacal smell. You may estimate the intensity of the phosphatic disposition by the rapidity with which the urine becomes alkalescent. Occasionally the salt is so abundant that it is thrown down while the urine is still in the bladder; and the last portions of the issuing stream look milky.

Any thing which tends farther to depress the powers of the system will aggravate the phosphatic diathesis. When you find that your patient passes urine such as I have been last describing, which does not redden litmus paper, but on the contrary turns litmus paper that has been reddened by a weak acid, blue again, or even in some cases is alkaline enough to make turmeric paper brown—in such cases you must cautiously abstain from all remedies that are calculated to lower the vital powers; from saline draughts, and alkalies of all kinds; from mercury and colchicum: from bleeding; and even from active purgation; or you will add to the patient's dangerous weakness; and promote the more abundant deposit of the alkaline phosphates. But you may do more than abstain from what is hurtful: you may counteract the phosphatic tendency by a generous diet and by the exhibition of tonic medicines; bark, wine, and acids; the muriatic acid, or the nitric, may be given in such cases with vast advantage sometimes. Opium is also a remedy to be employed in this form of disease. No single drug probably has so much power in rendering alkaline urine acid; as opium. And it is indicated for other reasons; it composes the nervous anxiety to which these patients are mostly a prey.

I should state that the tendency to deposit the mixed phosphates, though sometimes idiopathic, is much more often consequent upon local disease in some part of the urinary organs, especially in the bladder and pros-

tate gland. It is also a frequent result of certain injuries of the back.

There is yet another diathesis sufficiently common and important to claim your best attention. I mean the *oxalic*: in which there is a tendency to the formation, in the kidney, of the oxalate of lime, or *mulberry calculus*; an epithet derived from the occasional resemblance of the concretion to that fruit, in respect to colour and inequality of surface. This diathesis is not so obvious as the other two, but it is no less real.

The urine differs much in its sensible qualities from that of both the preceding varieties. Unlike the urine of the phosphatic diathesis, it is bright and clear; unlike that of the lithic, it is remarkably free from sediment. The mulberry calculus is solitary also; or recurs at long intervals; and the diathesis prevails chiefly during the prime of life. In both these particulars the contrast with the lithic diathesis is striking.

The persons who manifest this disposition are usually dyspeptic; sometimes very much so, sometimes very slightly. They are uneasy during the assimilation of their meals; suffer flatulence when the stomach is empty; prefer vegetable diets to animal; are fond of sweets, especially of sugar. They are liable to boils and carbuncles, and to scaly cutaneous eruptions. According to their original temperament, they are nervous and irritable, or dejected and desponding in mind. A nephritic attack relieves them from all this discomfort for years perhaps. When the oxalic diathesis is strongly marked, the skin, Dr. Prout says, "is apt to assume an unnatural appearance difficult to describe, but the colour of which may be said to vary from dull greenish yellow in the sanguine, to dark olive or livid in the melancholic temperament."

The formation of the oxalate of lime within the body depends either upon the non-assimilation of oxalic acid taken with the food, or upon the mal-assimilation of saccharine aliments. Hence, as a general rule, both curative and prophylactic, *sugar* and other saccharine substances should be rigidly excluded from the diet of these patients. They should avoid, also, all kinds of fermented liquor. The young stalks of the *rhubarb*-plant, which of late years have come into such general use in this country for tarts in the spring; and *sorrel*, of which our neighbours, the French, consume a good deal in salads, and in other ways; both contain oxalic acid: and *hard water* contains lime. Dyspeptic persons who drink such water, and eat such articles of food, and are thus daily introducing, without suspecting it, the constituent ingredients of the mulberry calculus, are very likely indeed to incur the pain, and the exceeding peril, of a

renal concretion of that kind. You must see, therefore, the great importance of detecting the oxalic diathesis; and of forbidding, to those who have it, all such viands as contain the oxalic acid, and of recommending them to use pure water, even distilled water, for drinking. Animal food, and the stronger farinaceous matters, are best for them.

With respect to direct remedies for this diathesis, Dr. Prout tells us that he has seen more benefit derived from the mineral acids, alone or combined with tonics, than from any other. But the effects of these acids must be watched: and when they begin to produce a deposit of the lithate of ammonia, or of lithic acid, their use must be suspended. He recommends to patients who happen to be at a distance, the muriatic, or nitro-muriatic acid, till the lithate of ammonia, or lithic acid, begins to appear in the urine; or for a *month*. "By adopting," he says, "such a course of acids three or four times in the year, and by carefully-regulated diet, I have seen the diathesis gradually subdued, and at length removed altogether."

These observations will serve, I hope, in some degree, as landmarks, to guide your treatment of patients labouring under renal or vesical calculi, or presenting symptoms such as justify the apprehension that such fearful disorders may occur. It is impossible for me to do full justice to this interesting subject in these lectures; and I must refer you, for more minute information respecting it, to Dr. Prout's invaluable volume, and to Sir Benjamin Brodie's most instructive book on the *Diseases of the Urinary Organs*.

## LECTURES

### ON THE

## ANATOMY AND PHYSIOLOGY OF THE INTESTINAL CANAL;

MORE ESPECIALLY OF ITS MUCOUS MEMBRANE.

*Being the Croonian Lectures for 1842, delivered at the Coll. of Physicians,*

By R. B. TODD, M.D. F.R.S.

Professor of Physiology in King's College, London, and Physician to the King's Coll. Hospital.

### LECTURE II.

THE structure of the alimentary canal, which I propose to consider in the present lecture, is essentially the same throughout the vertebrate classes. Its walls are formed by three planes of membrane, connected by intervening layers of cellular tissue. These are the serous, the muscular, and the mucous tunics.

The external tunic, or the *serous*, needs little remark. It is so adapted, that,

while it involves the intestine, it yet offers no obstacle to the rapid distension of any portion of it. This is especially conspicuous in the small intestine, where the serous membrane, in its passage from the abdominal wall over the intestinal convolutions, forms a fold of considerable depth, the mesentery, between the layers of which the distended intestine finds a ready passage. The mesocola, or folds connecting the several portions of the colon to the abdominal wall, similarly favour distension, but to a much less degree.

From the peculiar manner in which the serous membrane is reflected upon the intestine, it is evident that it cannot form a complete covering to it. Along the line at which the mesentery in the small intestine, and the mesocolon in the large, adhere to them, a space is left not immediately covered by serous membrane. Here the vessels lie, and give off their branchings, to supply the other tunics.

In two parts of the intestine the serous covering is very imperfect; these are the duodenum in its middle and inferior thirds, the posterior surfaces of which are closely connected, in the greater part of their extent, to the wall of the abdomen; and the rectum, which, to a pretty similar extent, and in a like way, is left uncovered by serous membrane. Hence the operation of paracentesis vesicæ may be performed, in the latter intestine, with impunity as regards the peritoneum.

The descending colon is uncovered posteriorly to a considerable extent; and Amussat has ingeniously taken advantage of this fact to open the intestine here through the posterior wall of the abdomen, with a view to establish an artificial anus, in cases of permanent obstruction in the lower part of the large intestine, or of imperforate anus. The operation has now been sufficiently frequently done, in France and in this country, to demonstrate its practicability; and to show that it may, in some instances, be resorted to with benefit.

The *muscular* tunic of the intestine is developed in two planes; an external one, consisting of longitudinal fibres; and an internal, composed of circular fibres. The different arrangements, which these two layers of the muscular coat exhibit, in the large and in the small intestine, constitute a very manifest feature of distinction, between these two divisions of the canal. In the small intestine each layer is continuous all round the intestine; in the large intestine the longitudinal layer is developed in three bands, which commence at the root of the vermiform appendix of the cæcum, and extend in this form to the rectum, where they become expanded, and form a continuous tunic, as in the small intestine. These bands, being shorter than the intestine to

which they are applied, cause numerous puckerings of it in the transverse direction, with bulgings between them, which are the cells of the colon.

In the small intestine, the muscular tunic is most developed in the duodenum; in the large, it is thickest and strongest in the rectum.

I have said that the three planes of membrane which compose the intestinal wall are connected by intervening layers of fine cellular membrane. That which connects the mucous to the muscular tunic is deserving of a special description. It is the submucous cellular tissue, the layer to which Willis gave the name "*tunica nervea*." It is composed of a very fine areolar tissue, and is the nidus to support the numerous blood-vessels, absorbents, and nerves, which are necessary to the perfect organization of the mucous coat. Its characters are nearly the same throughout the whole intestinal tract; but it seems a little more abundant in the small, than in the large intestine. The seeds of morbid change are generally sown in this tunic, as might be presumed from its more immediate and extensive connection with the blood-vessels, on which the nutritive processes depend.

The *mucous membrane*, or most internal tunic, exceeds the others considerably in length. Hence the necessity of its being thrown into folds, that it may be conveniently packed into a smaller extent of space. Throughout the intestine, in the human subject, these folds assume the transverse direction, and in the latter part of the duodenum and in the jejunum, they exhibit considerable regularity. Here they form valvular processes, projecting more or less into the cavity of the intestine. These folds were denominated *valvulae conniventes* by Kerckringius, and still retain that name, although they evidently do not perform the office of valves. They are absent, or are very imperfectly developed, in the first portion of the duodenum, and also in the lower part of the ileum. It is worthy of remark, that these *valvulae conniventes* are peculiar to man. The folds of the mucous membrane of the large intestine likewise assume the transverse direction. They form large partitions between the cells of the colon, and they result from the puckering up of the intestine by the longitudinal fibres, and its constriction at various places by circular fibres shorter than the rest.

The next subject which ought to engage our attention is the minute anatomy of this important tunic of the intestine. Before entering upon the particular description of it, however, I propose to make some observations on the structure of the mucous membranes in general.

Mucous membrane, as has been long known, presents marked analogies, in point

of structure, to the skin. It is, like the skin, a covering; the internal integument, while the skin is the external one; it is continuous with the skin at the various orifices—the mouth, anus, prepuce, &c. It is prolonged into the ramifications of the various glands connected with it, as the salivary glands, liver, &c. as the skin is prolonged into the glands connected with it, the sudoriferous and sebaceous glands.

The continuity of these two membranes being clearly established, the one lining the interior of the body, and the other its exterior, it is evident that they must enclose all the other textures, muscles, vessels, &c. between them. These parts are all connected with the deep or attached surfaces of these membranes: the vessels, nerves, lymphatics, reach each by its adherent surface. Hence the free surface of each may be said to constitute the exterior of the body; that is to say, all matters connected with the cavity of the intestine, or the free surface of the skin, may be regarded as outside the body. Nor is it difficult to conceive that the one membrane, if placed in the position of the other, might perform its functions, and *vice versa*, and by a stretch of imagination, one might suppose that, were it possible to turn a man inside out, the mucous membrane would perform the function of skin; or the outer integument that of mucous membrane. As, indeed, Trembley affirmed took place in the polype: when it was turned inside out, its external covering, now become internal, took on itself the secreting and digestive action; and it often happens that a long protruded portion of mucous membrane, exposed to the action of the air, acquires much of the appearance, and many of the characters of skin.

A careful examination of the intimate structure of each of these membranes, and a comparison of them in the various situations in which they occur, not only completely establish the analogy between skin and mucous membrane, but demonstrate their continuity in a manner hitherto unknown to anatomists, and prove them to be different parts of one and the same membranous expanse, modified according to the office specially assigned to each. It is true that Bichat and others had regarded these two membranes in this light, but since their views were based on the indications of a coarse anatomy, and since, from their not having availed themselves of the microscope, they were unable to obtain a minute anatomical analysis, they failed in demonstrating, what they had so happily surmised.

In the description I am now about to give, I have great pleasure in acknowledging the assistance I have derived from the researches of my valued friend, Mr. Bowman, whose excellent investigation of the minute

anatomy of voluntary muscles is now well known to anatomists\*. In the present account, however, I shall chiefly follow my own observations.

I have said that mucous membrane lines the interior of the body, and that it permeates the ramifications of the elementary tubes of which the glands are composed. It, indeed, forms the walls of those tubes, and to analyse its structure, we cannot do better than examine one of them with high powers in the microscope. The kidney affords a favourable opportunity for this purpose, and in its *tubuli uriniferi*, we shall find the elementary constituents of mucous membrane. Let me here remark, that all examinations of this kind ought to be made on parts quite in the fresh state, for the cohesion of the minute elements of this texture disappears very soon after their vitality†.

It had been ascertained by Henle, that the wall of a uriniferous tube is composed of two elements—a transparent membrane, and an epithelial covering; and to Mr. Bowman is due the merit of having shown, that these elementary parts exist, wherever true mucous membrane is found, and that skin is similarly compounded.

The primary, and most essential of these elements is the transparent membrane. It affords, perhaps, the simplest and most beautiful example of a membranous expansion which can be met with in the body. It forms the basis, on which the epithelial element is deposited; and to it the mucous membrane owes whatever cohesive power, strength, or other physical property, it possesses. Hence Mr. Bowman has given it the appropriate name of *basement membrane*; and by this name I shall designate it in the remainder of these lectures. The basement membrane is homogeneous, perfectly transparent; the highest powers of the microscope cannot detect in it any definite arrangement of particles. The Germans would call it structureless (*strukturlos*). We are not without examples of the occurrence of a similar texture elsewhere in the body. The transparent tube, that envelops the fleshy elements of the primitive fasciculus of voluntary muscle, presents precisely the same characters. The wall of the nerve

\* Since this lecture was delivered, Mr. Bowman has published an able article, on Mucous Membrane, in the *Cyclopædia of Anatomy and Physiology*, Part XXIII.; to which the reader may refer for details beyond the scope of this lecture.

† The structure of mucous membrane has recently been described by a distinguished anatomist, from preparations made by prolonged maceration! I have no doubt that, if M. Flourens would examine, with the microscope, the layers which he has so skilfully dissected, he would find that they are composed of areolar tissue.

tubule, which contains the soft neurine, is equally transparent and structureless: so, also, are the posterior layer of the cornea (*membrana Demoursii* of the French), and the capsule of the crystalline lens.

The basement membrane does not admit vessels into its texture. These ramify on its deep or parenchymal surface, and are supported by the submucous cellular tissue, very distinct in the intestinal canal, or, as in certain glands, by a soft cytotblastema, which seems to be derived from recently effused *liquor sanguinis*, and from which probably the basement membrane and the epithelium derive their nutrition and growth.

FIG. 1.

*Human Kidney Tubule, magnified 300 diameters.*

c, basement membrane, from which the epithelium has been detached.

The basement membrane may be readily seen in other parts besides the kidney tubes. In the tubuli seminiferi of the testicle it is highly developed, and of considerable thickness (fig. 2). In the glands whose tubes

FIG. 2.

present vesicular terminations, it is also highly developed, as in the pancreas or salivary glands (fig. 3). In the Meibomian

FIG. 3.

*Terminal Vesicles of Pancreas of Dog.*

a a, basement membrane.

glands, it may be very distinctly seen; also in the tubes of the stomach, especially towards their deep, or adherent extremity\*.

Upon the basement membrane, the epithelium is formed, and is deposited in one or more layers. It is entirely composed of nucleated cells, varying much in size and shape, according to the manner in which they are packed, and the disposition of the mucous membrane, of which they form a part. To the consideration of this highly important element we shall return by and by.

A minute examination of the skin will enable us to see that it is constituted in a precisely similar manner to mucous membrane. According to the account generally given by anatomists, skin consists virtually of two layers, chorion and epidermis, the rete mucosum, which is counted a third layer, being now acknowledged on all hands to be only the recently formed epidermic cells, immediately applied to the papillary surface of the chorion. The chorion is described as a fibro-cellular texture, on the free surface of which, papillae are developed.

A vertical section of the skin (and it is best to select a specimen from a situation where the papillae are developed), when examined by a high power in the microscope, shews three distinct layers: first, epidermis, deposited in a series of lamellae, and distinguishable by the scale-like character of its component particles; second, a thin, extremely delicate, homogeneous, and transparent membrane, in every respect precisely similar to the basement membrane just described; and, thirdly, a layer of interlacing fibres, in which the elementary fibres of areolar tissue, and of the yellow elastic tissue,

\* I am satisfied that Wasmann is incorrect in describing the dark part of the mucous membrane in the pig, as composed solely of epithelial cells. These columns are, as throughout the stomach, contained in tubes of basement membrane, which I have seen several times.

abound, and which are destined to connect the skin to the adjacent textures, and to support the vessels which ramify in great numbers among them. This last layer is nothing else than the *chorion* of anatomists; but it is evident that the true elements of the skin are the layers superficial to it, the basement membrane and the epidermis, as in mucous membranes; and that the so-called chorion bears the same relation to those elements of the skin, that the submucous cellular tissue does, to those of the internal integument: in short, that the chorion is the more superficial part of the *subcutaneous cellular tissue*, upon which the basement membrane is expanded, and in which the nutrient and absorbent vessels, and the nerves of the skin, ramify.

And strong confirmation of this view of the anatomy is derived from the fact that these elements are found in the various appendages of the skin, which may be regarded as true offshoots from it. In the sudoriferous glands, which exist in vast numbers throughout the whole surface of the external integument, the basement tissue may be seen forming the wall of the convoluted tube, of which the gland is composed. A highly magnified view of one of these sweat-ducts, from the pencil of Mr. Bowman, is given in fig. 4; and here the

FIG. 4.

*Sweat-duct from human axilla, magnified 300 diameters.*

A, transverse section. B, longitudinal view.

basement tissue may be seen, as a fine line, *a*, forming the exterior of the tube, and the globular particles of epidermis, *b*, constituting its innermost layer. The vessels from which the secretion is elaborated, ramify around the external surface of the basement tissue. The same disposition of epidermic particles within, basement tissue external, and vessels surrounding, may be seen in the sebaceous glands, and in the follicles from which the hairs spring.

I have given a rough plan of the anatomical disposition of these constituents of the skin in fig. 5, where the dark line, B, represents the basement tissue, elevated at certain intervals into conical projections to form the papillary structure of the skin, and involuted into the form of a spiral tube, S, the sudoriferous gland, or into that of a sac with vesicular bulgings, F, the sebaceous gland, or to form a hair follicle, H, with a papilla, H', raised from its blind extremity, from which the hair grows. The epidermis, E, covers this basement membrane, to a variable extent, wherever it exists, and beneath it lies the subcutaneous tissue, the chorion.

Let me refer to another diagram illustrative of the structure of mucous membrane, which may be advantageously contrasted with that of skin to prove their identity of composition. (Fig. 6.) Here the dark line, B, represents the basement tissue; E, the epithelial covering; and C, the submucous cellular tissue, containing V, vessels, and N, nerves.

The relation of the blood-vessels and nerves to the true skin and mucous membrane, is worthy of observation. It may appear startling to those who are accustomed only to the coarse anatomy of these textures, that I should class them as *extra vascular*. It seems, at first, impossible to believe this of tissues which have so long been regarded as the most highly vascular textures in the body; of which preparation after preparation is preserved in the various museums of anatomy, to exhibit their extreme vascularity, and about which the skill of a Malpighi, a Ruysch, and Leiberkühn, were so long employed. It is evident from the description I have given of these membranes, and the diagrams I have referred to, that the elements of them are not *penetrated* by vessels, and that therefore they must lie exterior to the vascular plexus by which they are supplied, and a comparison of the measurement of the basement tissue will shew that blood-vessels cannot penetrate its substance. In the tubes of the testicle the basement membrane measures in thickness about *rebus* of an inch, but the smallest capillary vessel has a diameter of rather more than double that size. That these membranes require, for their nutrition and their other functions, a capillary plexus of great extent, is perfectly true; and that the seat of that plexus is the submucous or subcutaneous tissue, and not the mucous or cutaneous, I conceive to be abundantly proved by the observations I have above detailed. And the extreme tenuity of the proper elements of the skin and mucous membrane will sufficiently explain, why the vessels appear so superficial, when an injected specimen of these textures is examined.

The extent to which we are now able,

FIG. 5.—Diagram showing the basement membrane and epidermis of the skin, and its involutions to form the sweat-duct, the sebaceous glands, and hair follicle.

FIG. 6.—Diagram of simple expanded mucous membrane.

through the improvement of the microscope, to carry our anatomical analysis, by the aid of high powers, will serve to remove much of the vagueness of our views as to the relation of vessels to the elements of tissues. I have no difficulty in stating that not only the ultimate but the proximate elements, of all the tissues are *extra-vascular*; and that the tissues hitherto admitted by most anatomists, as of this kind, are mere products of a process of secretion. Cuticle, for example, nails, hairs, epithelium, horn, are secreted by the tissue on which they rest, and are separated from the vessels by that tissue. In mucous membrane and skin, however, the vessels come in immediate contact with the basement membrane, but do not penetrate it. In muscle, the elementary part, the primitive fascicle, composed of a sheath containing the sarcoous elements, is not penetrated by the nutrient vessels: they ramify in the interval between the fascicles. In the analogous tissue, nerve, the nerve-tubes containing neurine, do not admit vessels: they are extra-vascular. In bone the proximate elements are cylinders, the axis of each of which is pierced by a canal: the vessels are

lodged in the Haversian canals, and the osseous elements, nourished by the corpuscular canals, which are not blood-vessels, but which doubtless imbibe the nutrient fluid from the blood-vessels of the Haversian canals, are deposited around and between these canals. So it is with teeth: the dentine does not admit blood-vessels, but derives its nutrition from the vessels of the pulp and of the osseous cortex of the fang. In fat, again, the adipose membrane is as free from vessels as the sarcolemma of muscle, or the tubular membrane of nerve; but the vessels play around the vesicles which they form, as vascular circles.

Blood-vessels are every where surrounded and supported, more especially when they are destined for the nutritive process, by a soft blastema or elementary texture, either truly cellular, in the strict sense of that term, or areolar or fibrous. This is, no doubt, the seat of those changes upon which the growth and nutrition of the tissues depend. The blastema is itself the result, of an effusion of the liquor sanguinis, through the walls of the capillaries; and it is not improbable, that the same series of phenomena

(the formation of cytoblasts, of cells, and the ultimate transmutation of these cells into the elementary parts of the tissues) takes place in it, as Schwann has shown to occur in the primary development of the various textures.

And the views I have expressed, respecting the relation of blood-vessels to the tissues, are quite in accordance with what we know to take place, at the early formation of the embryo. The vascular system we know to be developed on a plane, intermediate to those, in which the various tissues appear. The so-called serous lamina, with which the development of the skin, nerves, muscles, &c. is connected, and the mucous layer, which gives rise to the internal integument, must therefore enclose the vessels between them; the vessels are consequently connected with the parenchymal surface of each layer; and this relation they continue to preserve in adult life.

I would propose the following subdivision of the tissues, founded upon the relation of the vascular system to them:—

1. Those tissues which are merely secreted products, and which are therefore separated by an intervening membrane from the vessels, *e. g.* epidermis, epithelium, hair, nails, hoof, horn.

2. Tissues whose proximate elements are in contact with vessels, but are not penetrated by them; *e. g.* muscle, nerve, mucous and serous membranes, skin, bone, cartilage, fibrous membrane.

3. Tissues which accompany and surround vessels, forming a blastema for the nutrition of other tissues, or a support for the vessels themselves, or adapted as a connecting link with other textures; and in this class I would enumerate the soft gelatiniform cellular membrane; and the areolar tissue.

But to resume the proper subject of my lecture.

The plan which I have given in the diagram, of mucous membrane, represents its simplest disposition, as a mere expanse. We find it, however, much more extensively arranged, in a complex manner, so as to obtain a great extent of surface, with less occupancy of space. It is then involuted, so as to form tubes, simple or branched, or mere depressions; or villi projecting into the cavity of the membrane in a manner analogous to that shown in the diagram of skin. This complex form of mucous membrane is represented by a diagram, fig. 7. All the elements of the mucous membrane will be found in these involutions, whether

FIG. 7.—*Diagram of an involuted Mucous Membrane, to shew the continuation of its elements into the foldings.*

E, epithelium; B, basement membrane; C, submucous tissue; V, vessels; N, nerve.

they form simple follicles, or villi, as in the diagram, or more complicated branchings, as in the ramifications of the secreting tubes or glands. (This point, however, has not yet been satisfactorily made out as regards

the ultimate branchings of the hepatic duct.) The apparent thickness, which the mucous membrane exhibits in some situations, is owing to these involutions being closely packed together, in a direction perpendicular

to the submucous cellular tissue, as is manifest in that of the stomach, and intestinal canal. In other situations, as in glands, the involutions of the mucous membrane are kept very much apart, by the intervening vascular ramifications, and their accompanying blastema, or cellulo-fibrous tissue. To judge of the real thickness of an involuted mucous membrane, we must carefully examine thin vertical sections of it under high powers.

*Of epithelium.*—The epithelium constitutes a highly interesting and important element of mucous membrane; whether we regard its immense quantity, or the rapidity and extent with which it is being continually thrown off, and reproduced. It is now known that the presence of this product is a characteristic of all secreting surfaces, serous, as well as mucous and cutaneous; and the doctrine is daily gaining ground, that by it the separation of, at least, the organic elements of the secretion are effected. We know that the epidermic scales are continually separating to be succeeded by new ones: so it is with the epithelial particles, whether in glands or on surfaces. The mucus which is formed on the surface of all mucous membranes is no more than the debris of those epithelial particles, combined with moisture, which have been pushed off by a new deposit on the surface of the basement membrane.

The newly deposited epithelium is generally, if not always, globular or spheroidal in its form; but it afterwards becomes modified in its shape by pressure, and the mode of packing.

When the surface is flat and expanded, the old epithelium assumes a flattened form, and is that variety which Henle calls *pflaster epithelium*, consisting of scales, generally polygonal, containing a nucleus, and resembling very closely the scales of the cuticle, which are formed and flattened in a precisely similar way (fig. 8).

FIG. 8.

*Epithelium scales detached from the surface of the uvula, magnified 300 diameters.*

In fig. 8 some epithelium particles of the scaly kind are shown; and in fig. 9 is an illustration of the manner in which these particles become changed from the spherical to the scaly form as they lose their water,

757.—xxx.

and are compressed by the newly-deposited layer beneath.

FIG. 9.

*Vertical section of epithelium of the mouth, showing successive layers, and the flattening of the superficial ones.*

aa, superficial scales. dd, recently formed ones.

In most of the glands the epithelium retains its globular or spheroidal form, owing probably to the absence of compression and evaporation; but in the kidney, where the water excreted at the distal extremities of the tubes flows over, and compresses the newly deposited epithelium, the particles appear slightly flattened.

On the involuted mucous membrane of the intestines and stomach, and on that of the uterus and of the lungs, we find a third variety of epithelium particles, to which Henle has given the name *cylindrical*, but which I prefer to designate *columnar*. Each particle tapers at its adherent, and presents an expanded polygonal base at its free extremity: when viewed attached to a surface, these particles appear like a number of little pillars or columns placed perpendicularly to it. They may be best seen in the villi of the intestine, or in Lieberkühn's follicles; and their mode of arrangement is explained by the diagram of involuted mucous membrane (fig. 7.)

It is difficult to account for the peculiar form of this variety of epithelium: I am disposed to believe that it may be explained by the particles being arranged round a cylindrical surface in a radiating manner, and being therefore subjected chiefly to a lateral pressure.

Although I have stated that epithelium may be regarded as a secreted product, the cell-like structure of its particles shows, that its mode of formation is similar to that of the more complex tissues; and, therefore, that it cannot be regarded at first merely as a collection of excreted lifeless particles. It is, at its first formation, part and parcel of the living organism, and its particles have their appropriate vital endowments. And if the morphological character of the tissue were not sufficient to prove this, it is abundantly evident from the singular phenomenon which is always associated with it: I allude to the

2 C

rapid movement of the vibratile cilia, which grow from it, generally from the columnar

b, From bronchial membrane.

variety, and which seem to derive their motor impulse, from the vital power of the particle, to which they adhere. A few of these particles, from the frog's mouth, will continue to exhibit the motion of cilia for many hours together under the microscope, provided they are kept moist, although all connection with the surface, from which they sprang, has been destroyed.

In my next lecture I shall apply these general observations to the particular anatomy of the intestinal mucous membrane.

## DIAGNOSIS OF MALIGNANT DISEASE OF BONE.

*To the Editor of the Medical Gazette.*

SIR,

I HAVE often availed myself of the pages of your journal to communicate to the professional reader facts and observations for which I had not a nook in any immediately contemplated publication; and you have already been good enough to insert some exemplifications of malignant disease in bone supplementary to what I have said on that subject in my *Outlines of Pathology*. I therefore now offer you an account of the most interesting case of this nature which has come before me.

The interest which attaches to this case is twofold; being, 1st, in its strongly marked but anomalous features, and consisting, 2dly, in the difference of opinion which these anomalies have led to among the best professional authorities. These authorities I will not name, but employ the first letters of the alphabet, being not their initials, to indicate them. There is no breach of

professional confidence in this matter, as the counter-opinions of each have been, with the knowledge of the others, declared at the time to the patient and his friends; and, indeed, as the case is not yet terminated, either side may yet be right.

A young man, aged 28, one of a numerous and healthy family, whom, however, with other members of it, I had before attended for various ailments, about February in last year, found that in walking his left knee would become weak and uneasy: it seemed to give at the back part. Gradually it became painful in addition, and, getting worse after some weeks, it became one night of a sudden slightly contracted; and there was some diffused swelling about the back part. The patient was under the care of a very intelligent practitioner in his neighbourhood; but he now wished to have more advice; and, as I was then absent from London, he consulted an eminent surgeon, whom I shall call A.

A recommended an alterative course of sarsaparilla and liquor potassæ, which the patient pursued without advantage: then, one eye becoming inflamed, and iritis threatening, calomel was added in repeated doses, so as quickly to affect the gums. The inflammation in the eye was thus dispersed; but the knee became worse than ever. About this time, the end of May last year, I returned to town, and the patient placed himself under my care.

He described himself as suffering most severe pain in the knee, within and through it, vaguely diffused, increased by moving the joint, but not by pressure upon the articular surfaces. The pain was most intense at night; the aching stretched down the leg-bone. There was no fluid in the joint, but there was general swelling about the popliteal space and hamstring tendons. The knee was moveable, but drawn to an angle of 150° or 160°; it gave the patient pain to alter the degree of flexion. He was confined to bed. He obtained some relief by continued hot fomentation.

The surgeon who lived in his neighbourhood had conjectured, very plausibly, that the complaint might have a syphilitic origin; and the supervention of iritis confirmed this view: but on the other hand, the pain continuing

and being aggravated after the gums were touched, and the absence of sore-throat or skin eruptions, were at variance with this supposition. A, I understood, had been unwilling to give a name to the disorder, but thought it more like rheumatism than any thing else; and the same view occurred to myself, and I thought it possible that it might have a gonorrhœal origin. I ordered leeches to be applied and repeated; the hot fomentation to be continued; wine and meat to be discontinued, and low diet substituted; and small doses of colchicum twice a day, with laudanum at night and some aperient with a few grains of blue pill. Under this treatment the patient improved considerably and rapidly; and after a month I began confidently to hope that he would get rid of the remaining pain, and of the swelling, and recover the use of his knee.

But now, about the beginning of July, a blister having been, by my advice, applied to the middle of the outside of the thigh, quite off the swelling, the patient ceased to improve. The blister was sore, and fretted him; the swelling, which had hardly lessened, became more uneasy. The blistered surface healed, but the knee got worse; in two or three weeks the swelling there and the pain had considerably increased, and leeches re-applied were of no service. Then I made several small issues on the inner aspect of the knee, which the patient fancied did him good; but the general swelling behind the knee increased, and now encroached forward over the inner condyle; there was more heat about the knee, and the subcutaneous veins were distended enough to be visible; the pain was only relieved by large doses of laudanum at night: during the day he now took, twice, a saline draught, containing three grains of the iodide of potassium. For a few days I entertained the hope that the swelling would suppurate.

But now a new view forced itself upon my conviction. I could make out, through the general swelling, what seemed the posterior aspect of a defined tumor, occupying the popliteal space, firm and immovable, growing, I presumed, from the posterior surface of the femur, immediately above the condyles, and pressing to either side the hamstring muscles: the popliteal artery

being to be felt upon it, seemingly elevated to no great distance below the skin. The tumor was masked by considerable general doughy swelling, especially upon the inner condyle, the inner hamstring muscles, and vastus internus.

Combining these present features with the history of the case, I came to the conclusion that the disorder must be malignant disease of the femur, probably (as the most frequent form) medullary sarcoma; but perhaps (to which I rather incline, from the prominence and firmness of the popliteal tumor at that time) one of the two forms of osteo-sarcoma—the cartilaginous or the gelatinous.

I felt it my duty to break this painful intelligence to the patient, and recommended him immediately to see A again; and two other surgeons, whom I will call B and C, were likewise fixed upon. At the same time I altered the general treatment; discontinuing the iodide of potassium, and giving him quinine, with meat and porter, to recruit his strength, for he had become thin, and pale, and worn, with low diet and suffering.

Of the three consultants, he first sent to B, who came and examined the knee, and expressed his apprehension that the complaint would indeed prove to be medullary sarcoma.

The patient then sent to C, who, after a careful examination of the case, in which he at first inclined to the supposition that the disorder might be inflammatory, concluded with the same formidable anticipation that a short time would prove the disease to be medullary.

And now an odd event took place. The patient was on the improved diet I had ordered, and seemed the better for it, when, on drawing himself into bed one night, he inwardly strained or somehow hurt the tumor, when the most excruciating pain followed, and lasted for some hours. But when he woke from the sleep which he had at last obtained through opium, the pain in the knee was much better; and in two or three days the general swelling was less; and some œdema of the foot, which had appeared, had very much lessened, and finally went away.

Then A was sent for, as a third consultant. After a full consideration of the case, he declared it to be his clear impression that the disorder was inflam-

matory only, and might terminate either by slow dispersion or by suppuration. Of course the patient was delighted at this mitigated sentence, and was most anxious that I should change the opinion which I had expressed. I told him I regretted that I could not; but that A's opinion was of much more value than mine, and more likely to be right, and that I most sincerely hoped that the end would prove me wrong. However, I advised that another opinion still should be taken. This, as it was natural, was not done, and the case was left to the judgment of A. This was towards the beginning of September. The patient now, I understood, continued better, in less pain, and the swelling, as I heard, had rather diminished. I heard again, that in November A had punctured the tumor deeply with a grooved needle; and that an artery seemingly had been opened, for the puncture had bled very profusely. The bleeding stopped with pressure, but there was rather more pain afterwards.

Then another surgeon, D, was consulted, who likewise gave it as his opinion that the swelling was inflammatory, and would terminate in an abscess. Finally, about March, another surgeon, E, saw the case with D, and declared it to be spina ventosa, and recommended pressure. This practice being resorted to, was followed by a great increase of pain and swelling; and at length, about a month ago, I was again sent to, the family being fearful that at last my original diagnosis would prove correct. I found the patient suffering severely, the knee of a vast size, from diffused general swelling and some synovia in the joint; leaving no doubt in my mind, at the first glance, that it was the malignant disease I had before supposed it, now at a more advanced stage; while no glandular enlargement having taken place in the groin leads me still to hope that the special form is the osteo-sarcomatous; although it is, of course, impossible now, and was formerly, with confidence to say of which kind of malignant disease the tumor consists. I found the patient, however, but half disposed to listen to my strong recommendation that the operation should be no longer deferred; and I therefore begged he would see another surgeon, whom I will call F. After some delay,

F was sent for, and pronounced the tumor to be medullary. B has likewise again been sent for, and has seen the patient, and passed the same sentence on the case. And D, I am told, has had the opportunity given him of puncturing the tumor, from which some grumous fluid alone escaped.

The patient, however, still hesitates, and puts off naming a day for the operation; for he is again in less pain; for leeches, which I recommended, and continued warm fomentations having been used, the knee is again a little easier and less swelled than immediately after the trial of pressure.

If the patient, as I trust he will, submits to lose the limb, I will communicate the result to your readers. He declares that he is now in my hands, and those of B, who, I may mention, is Mr. Stanley, and that he will adopt our advice; but I greatly fear he will not.—I am, sir,

Your obedient servant,  
HERBERT MAYO.

2, St. James's Place, May 22, 1842.

#### CASE OF OSSEOUS ANEURISM,

SITUATED IN THE INFERIOR THIRD OF THE FEMUR.

*To the Editor of the Medical Gazette.*

SIR,

SHOULD you deem the following case of sufficient interest, you will oblige me by giving it publicity in your valuable journal.—I remain, sir,

Your obedient servant,

HENRY HARGREAVES,  
Burnley, Lancashire, M.R.C.S.L.  
May 26, 1842.

*Case of Osseous Aneurism, situated in the inferior third of the femur, distending the whole of the popliteal space, advancing anteriorly, and causing great deformity of the right knee-joint, which was treated for diffused popliteal aneurism, by placing a ligature on the femoral artery in the superior third of the thigh; terminating in purpura and death.*

Jonathan Driver, aged 19, thin and delicate-looking, was admitted into the Union Workhouse, on the 5th of April last, under my care.

*History.*—About five months ago he injured the right knee, near the inner

condyle, by slipping over a stone bank. The accident gave him little inconvenience at the time, or on the following day, but at the end of five weeks he perceived a slight swelling situated on the inner side of the knee-joint, and occasionally communicating to the touch a degree of beating. This, however, was not at first attended with very great inconvenience, until the tumor gradually increased in size from the circumference towards the centre, which caused pain and stiffness from its bulk, and his incapacity from using it. In the commencement it was seen by a noted bonesetter; and two days before he was put under my care he was visited by a surgeon who said the swelling contained matter: he punctured it with a lancet, but instead of reaching pus, nothing but bright-red blood followed the incision. Present symptoms and appearances of the limb are: general constitutional derangement, with dry skin, furred tongue, thirst, small and rapid pulse, insomnium. Ordered the following:—

℞ Mist. Febrifuga, ℥vj.; Antim. Tart. gr. i. ft. mist. Coch. ij. L. 3tiā quaque horā sumend.

℞ Hyd. Chlorid. gr. v.; Morph. Ant. gr. 4, ft. pulv. horā somni sumend.

℞ Haust. Sennæ primò mane sumend.  
Lotio evap. genu.

Absolute rest and low diet.

The tumor has attained an enormous magnitude: the circumference round the knee joint measures 24 inches, whilst the normal side is 11 inches; this difference causes a vast deformity of the whole limb. It is accompanied with a diffused hardness, as if it was caused by deposited fibrine, which fills up the whole of the popliteal space, extending as high as the inferior third of the thigh, and advancing towards the internal condyle and front of the joint, which is very considerably infiltrated with serous fluid, which gives to the tumor in the latter situations a globular shape, and a very elastic feel on pressure: on mediate auscultation there is a dull but distinct pulsation heard in the course of the popliteal artery, but neither pulsation or tremor is communicated to the touch. A very indistinct pulsation could sometimes be heard at the internal condyle, but it could not be distinguished at all times. The stethoscope was only of negative assistance, and did not enable me to detect any abnormal sound. The

nerves, veins, and lymphatics, are exposed to a very considerable degree of compression; the normal relations of the bones and muscles are altered; the motions of the joint are impeded and painful; there is œdema of the leg and foot, with pain and numbness; the superficial veins are greatly enlarged, but there is no discoloration of the integuments; the limb feels cold; pressure produces no perceptible change in its volume; the inguinal glands are not affected. After very carefully examining the case, on three separate occasions, I came to the conclusion (although it was surrounded with a great deal of ambiguity), that it was a diffused popliteal aneurism, and determined upon tying the femoral artery, before having recourse to amputation, the only other alternative; more especially should the grooved needle on being introduced favour that opinion. A consultation was held with three other surgeons on the 10th of April, when the propriety of the proposed operation was assented to. The patient offered no objections to any operations being performed which might favour the chances of retaining the limb, but objected most strenuously to have the limb amputated, although the risk, probable result, and consequences, were fully stated to him.

Before proceeding to tie the artery, which was on the 11th April, a grooved needle was introduced into the swelling over the inner condyle, when a quantity of serum, mixed with arterial blood, flowed along the groove. The artery was exposed in the superior third of the thigh; not more than a tea-spoonful of blood was lost during the operation; and nothing unusual occurred. The wound was dressed in the usual way, and a flannel roller placed on the member. In the evening of the same day there had been no bleeding from the wound. He complains of great pulsation in the femoral artery, with alternate heat and cold in the limb. Pulse 90.

To have tea, gruel, and toast-water.

12th.—Slept but little during the night, although he had an opiate; pulse 100; tongue dry and furred; thirst; temperature of the limb natural; circumference 22½ inches.

Ordered ℥ss. Ol. Ricini.

13th.—A little sleep during the

night; pulse 95; tongue moist; bowels relieved; circumference 21 inches.

To have a few oranges. Arrow-root.

14th.—Slept better; pulse 90; tongue clean; circumference 20 inches; appetite good.

15th.—Wound in thigh to be dressed; it looks healthy. Pulse 95; bowels free; restless; circumference 18½ inches; œdema of the leg entirely subsided.

R Hyd. Chlorid. gr. iv.; Morph. Acet. gr. j. ft. pulv. divid. in chartâ viij. 1 quâque 6tâ horâ sd.

16th.—Pulse continues quick; sleeps better; appetite very good; circumference 17½ inches,—after which time it did not diminish materially.

Ordered rice, milk, eggs, and sago gruel.

17th.—Pulse small and rapid; vesications have appeared on the surface of the tumor.

18th.—Wound looking healthy; pulse 95; tongue clean; sleeps well.

To have beef-tea.

19th.—The tumor feels considerably softer above the knee, and in the popliteal space. Pulse 90; bowels regular.

To have a pint of porter daily.

20th.—In every respect progressing favourably.

22d.—Sleeps well. An attempt was made to remove the ligature, which remained firmly attached.

Omit the calomel and morphia.

24th.—The vesications have entirely disappeared; the tongue looks clean; skin cool; pulse 85. Rather restless.

To have an opiate at bed-time.

25th.—Sleeps better; in other respects the same as yesterday.

26th.—The wound is nearly healed, but the ligature is firmly attached.

27th.—Slight ulceration of the cuticle; pulse 90; thirst; pain in the limb.

R Mist. Febrifuga cum Antim. Tart. 3tiâ quâque horâ sd.

R Ol. Ricini, ʒss. statim sd.

28th.—Slight epistaxis, which yielded to styptics; there is a little ichorous discharge from the ulcerated integuments, and a sensation of fluctuation. Epistaxis has returned; plugged the anterior nares with lint soaked in Tr. ferri sesquichlorid. The limb is gra-

dually enlarging. A consultation was again held concerning the propriety of removing the limb; this step, however, was not considered admissible, for, on examination, petechiæ were discovered on the affected member, which rapidly spread over other parts of the body; and the disease very speedily shewed itself to be genuine hæmorrhagia petechialis. The mucous membrane of the mouth was studded with petechiæ, and the gums were disposed to bleed.

R Acet. Plumbi, Tr. Opii, et Acid. Acetic. were given in combination. Port-wine negus, and strong animal jellies.

Haust. Anodyn. h. s., sd.

29th.—Ulceration of the integuments spreading superficially; pulse small and rapid; petechiæ more numerous. The hæmorrhage from the mouth and fauces is constant; great pain in the limb; little or no sleep; the swelling has increased to its original size.

Haust. Anodyn. rep. st.

30.—Seems very much exhausted, with cold extremities; pulse scarcely perceptible; intellect not in the least impaired; gradually sinking.

May 1st.—Died this morning, about 8 o'clock, A.M. There was no admixture of blood either in the urine or fæces.

*Post-mortem appearances eight hours after death.*—On making an incision, and exposing the popliteal space, a quantity of serous fluid flowed out; on cutting deeper, I exposed a complete sac extending as high as the middle third of the thigh, which was full of a sanguineous fluid, and contained fibrous concretion, a semi-cartilaginous substance interspersed with a little ossific matter. The sanguineous fluid, which was of a very dark colour, independent of the other component parts occupying the sac, amounted to about four pounds. The lower extremity of the os femoris was not enlarged either above or below where the sac had made compression, and appeared to have undergone no change, but presented a honeycomb appearance where the tumor had exerted pressure, and which had caused partial absorption of the ossific matter in that situation. It was difficult to say whether the sac itself was composed of the periosteum, or had a distinct origin, but the tendons, muscles, nerves, and blood-vessels, did not present any abnormal appearance, or give the slightest grounds to

suspect that the affection had a malignant origin or tendency, as it chiefly contained a sanguineous fluid. The popliteal artery, vein, and nerve, were situated very superficially, and upon the sac. The wound made to expose the femoral artery in the operation had healed up, but the ligature was firmly attached; it was re-opened, and the lining membrane of the artery exposed above where the ligature had been placed, when a firm coagulum (of a pyriform shape) was discovered, completely plugging up the artery. It was about three-quarters of an inch in length. The sac had no communication with the popliteal artery, which appeared in a most healthy state. I feel sorry no general examination of the body was allowed. Even the examination of the morbid limb was done without the knowledge of the friends: no time for injecting the arteries could possibly be obtained, which preparation would most probably have facilitated our coming to a more definite and correct knowledge of the origin and progress of the morbid action. In short, the general appearance of the sac and its contents was exactly such as I have often seen when examining an aneurism after death.

**REMARKS.**—I have been induced to publish this very interesting case from the obscurity in which the principal symptoms were from the first involved; the rarity of its occurrence; the great difficulty in forming a correct diagnosis, in consequence of the enormous bulk it had attained, and its unyielding structure, when I first saw the patient; and more especially from its being connected with one of the most important operations in surgery. The post-mortem appearances have quite satisfied me that the disease was not of a malignant growth, as in that case it would have been formed of a different structure, would not have presented so uniform an appearance, and the morbid condition would have been more fully developed. There would also probably have been some fungoid excrescence protruding from the puncture made with the lancet, independent of the symptoms pathognomonic of malignant diseases. I had fully determined upon removing the limb as a last resource, but did not think myself justified in taking this step before I had tried the

effect of tying the femoral artery. The rapid diminution in the size of the tumor, and the favourable condition of the patient, for some time led me to anticipate a successful termination; but unfortunately the supervention of purpura rendered amputation impracticable, as it was evident the patient would sink whatever steps were taken. I cannot suppose that the small doses of calomel and morphia could have induced the purpuric tendency, which were prescribed with the view of anticipating inflammatory action—that the patient might the more readily have been brought under the mercurial action, should consequences have demanded it, for there was not the slightest approach to ptialism, and it was omitted altogether after a few days. I find the nearest description to the present case, spoken of, under the head of osseous aneurism, by Mr. Syme, of Edinburgh, in his valuable work on Surgery.

#### CONTRIBUTIONS

TO THE

#### CHEMICAL PATHOLOGY OF SOME FORMS OF MORBID DIGESTION.

BY GOLDING BIRD, M.D., A.M., F.L.S.

Member of the Royal College of Physicians,  
Physician to the Islington Dispensary, and  
Lecturer on Medical Physics at Guy's Hospital.

(Continued from p. 384 of preceding volume.)

In my previous papers I have particularly drawn attention to the characters of the fluid ejected from the stomach in those cases of gastric affection in which no evidence of organic, or at least of disorganizing, affection existed, and have stated, as the result of my own experience, that so long as no marked organic disease has occurred the vomited fluids are *always colourless*\*, and when possessed of acidity at all, never contain any considerable quantity of a free acid; care being taken to trust to chemical evidence, and not to the feelings of the patients, as our guide. When, on the other hand, mere functional lesion has given way to structural mischief, the vomited fluids become more or less coloured, not from the accidental admixture of bile or ingesta, but persistently so from the

\* Page 283 of last volume.

presence of a peculiar brownish colouring matter, most probably a modified form of the colouring matter of blood. The organic lesion need not by any means be actually seated in the stomach to produce this change, the same effect on the secreted fluids being produced by disease limited to the pyloric orifice, or even by organic mischief affecting the liver, or other organs in the neighbourhood, providing its effect be to obstruct the egress of ingesta from the organ.

To avoid any unnecessary repetition of cases bearing upon the same subject, I shall content myself with detailing one only at length, and giving an account of the observations I had occasion to make on the fluids ejected from the stomach.

CASE XVIII. — *Scirrhus pylorus.* — *Hæmatemesis and melæna.* — *Persistent brown acid vomitings.* — *Death.*

J. H., æt. 44, a fine, well-formed man, with a face presenting a remarkably sallow aspect, like that of malignant disease, came under my care in the summer of 1840. He was born in London of healthy parents, and no trace of hereditary disease existed in his family. When a boy of eleven years old, he became the subject of malignant disease of the right knee, for which he was admitted into Guy's Hospital, and the limb was removed by the late Sir Astley Cooper. For the last twelve years he has been employed as a tax-collector; previously, he worked as an engraver for ten hours a day, living very freely, and often escaping into the country to amuse himself with his gun. In these excursions he became exposed to great alternations of temperature, and lived irregularly. He never married; usually partook of at least two or three pints of malt liquor, and several glasses of gin and water, in the day. In 1836, he first suffered from pyrosis, the attack being preceded by burning heat at the scrobiculus cordis, and ending with gushes of limpid tasteless fluid. Of this ailment, which lasted about six weeks, he ultimately recovered under the care of Dr. Elliotson. From the period of this attack, he suffered severely from gastrodynia, which, although resisting the action of other remedies, generally yielded to nitrate of silver administered in small doses. Frequently during

these attacks, his evacuations were pitch-like, very probably from an admixture of blood. The paroxysms of gastrodynia have persistently got more severe during the last three years, never being absent for more than a few days, except in one instance, when they vanished for several weeks, which respite was attributed to the mental excitement dependent on a parochial election, in which he was much interested. In July 1840, he consulted Dr. Bright, who detected the previously overlooked malaria; he had just stepped into his gig on leaving Dr. Bright's house, when a sudden sensation of extreme faintness overpowered him, and a copious gush of blood rushed from his stomach. The hæmatemesis continued for some days, and reduced his strength so much as to confine him to his bed, and soon afterwards I was requested to see him (August 1840.)

On my visit, I found him labouring under intense burning pain in the region of the stomach, most intense at its right extremity, with frequent vomitings of very sour and bitter, but colourless, fluid, holding in suspension numerous brownish flocculi. He was often free from pain until he partook of food, and then the gastrodynia, with pyrosis, came on very quickly, and the moment he turned on his right side full vomiting always commenced, followed by an interval of ease, which generally lasted until he again took food. The evacuations from the bowels contained a considerable quantity of black pitchy matter, evidently changed blood. I succeeded in checking the melæna, and partially allayed the vomiting by the exhibition of oxide of silver, keeping the bowels free by sulphate of magnesia in acidulated infusion of roses. His strength gradually returned, and soon feeling well enough to go into the country, I lost sight of him until October.

Oct. 28. — During the last two months, he has suffered from frequent attacks of vomiting after his meals; these do not appear to be influenced by any modification of food, and, as a general rule, are less frequent when the bowels are constipated, and if, by any chance, he has passed a week without a motion, he has generally lost the vomiting altogether. He yesterday dined moderately, taking a mutton chop and a glass of ale; he felt comfortable, and

remained so until his tea, when he became uneasy, and about an hour afterwards was seized with intense pain at the epigastrium, with distressing flatulence and spasm, so intense that he was "bent double" by it, and appeared like a person suffering from colic. At half-past eight he vomited half a pint of very sour and bitter fluid. He went to bed, and immediately on lying on the right side a tremendous escape of flatus occurred, with gushes of fluid; not, however, experiencing the slightest relief until he arose, when the vomiting ceased. During the night he was so hysterical that he wept like a child. His face is much more sallow than when I saw him in the summer; his sclerotic is pearly; lips exsanguine; surface of the body unperspirable. He always suffered from an intense throbbing pain in the occiput on taking food. On examining the abdomen, a tolerably hard and well-defined tumor could be felt in the region of the pylorus: pulse feeble, thread like, but compressible.

R Hyd. Chlorid. gr. v.; Conf: Opii, gr. iij.; fiat Pil. statim. sumend. et post horam injiciend Enema Terebenthinæ.

R Morphine Hydrochlor. gr. iij.; Argenti Oxydi, gr. iv.; Ext. Conii, ℥ss. M. divid. in pil. vj.; sumat. j. 4ta. quaque hora vomitu seu dolore urgenti.

29th.—The bowels acted once, but scantily; intense gastrodynia came on in the evening, but no sickness until going to bed, and then the moment he turned on his right side violent vomiting came on, and lasted almost unremittingly during three hours, when he fell asleep, and awoke much refreshed.

Nov. 12.—From the date of last report he has been somewhat easier, occasionally passing a day without vomiting. After passing a tolerably comfortable day, he went to bed, and felt nearly free from pain until he turned on his right side; a gush of pale brown fluid nearly immediately rushed from his stomach: this was exceedingly acid and bitter. He encouraged the vomiting by copious draughts of warm water, and thus relieved the burning heat and gastrodynia which distressed him. During the vomiting he suffered severely from a twisting sensation about the umbilicus. In addition to the pills, he was

ordered counter-irritation over the stomach, and lime-water, with milk, occasionally. The bowels remained exceedingly constipated, and required, every two or three days, a purgative; but of whatever kind this may be, and whether administered as an enema or by the mouth, it invariably brings on vomiting during its action, or, if that were previously present, greatly aggravates it.

Nov. 17.—During the last few days he has been better, and remained to-day pretty well until tea-time, when, after partaking of a cup of warm fluid, violent gastrodynia and vomiting came on: altogether he brought up rather more than a gallon of fluid. On going to bed he was somewhat relieved, but during his sleep, on turning on the right side, the vomiting came on as severely as ever. He has emaciated greatly lately, and his face has assumed an active tint. I ordered an emetic of sulphate of zinc.

18th.—Under the influence of the emetic, he vomited about two quarts of brown acid fluid, in every respect like that brought up the preceding evening. He immediately afterwards ate a dozen oysters, and drank a little of Webb's magnesia-water, which often afforded relief to the gastrodynia and vomiting.

23d.—The bowels having been confined for some days, an enema containing an ounce of oil of turpentine was administered. This acted on his bowels without producing sickness. He went to bed, and, as invariably occurred on lying on the right side, a severe attack of vomiting came on, and about a quart of acid fluid rushed from the stomach. He is exceedingly exhausted; the surface is cold and clammy, but the gastrodynia remained so intense that, of his own accord, he took an emetic in the hope of getting some relief.

24th.—The emetic caused a considerable quantity of fluid, paler and less acid than usual, to be vomited.

Dec. 10.—From the last date this poor fellow has been rapidly sinking. His bowels never act without a purgative enema, which is administered about every three or four days, and always excites the most distressing vomiting. Some amount of rest is obtained by small opiate enemata, and his strength is supported by sipping jelly, beef-tea, and an egg beaten up with sherry. To-day he had another

terrific attack of vomiting, the character of the fluid being like the last. The tumor about the pylorus became decidedly more evident from his emaciation, and in about three weeks he expired, completely starved to death by the almost complete impossibility of getting food past the pylorus.

The post-mortem examination completely confirmed the accuracy of the opinion formed during life. The stomach was enormously distended, its greater curvature reaching nearly to the pubis: its mucous membrane was universally congested and softened. The pyloric orifice was so extremely narrowed, that the point of a probe entered it with difficulty: it was completely surrounded by a structure of scirrhus hardness, and about the size of an orange, which indeed formed the tumor detected on examination in the previous autumn. Several ulcerated patches existed on the gastric aspect of this scirrhus mass. No other disease was met with in the chest or abdomen. In the detail of this case I have not thought it necessary to give the daily reports, or to record the variation of treatment adopted; as all that I am anxious to do is to enable the reader to connect the characters of the vomited fluid with the progress of the disease. One point of great interest, which I cannot help alluding to, is the fact of the constant accession of vomiting whenever the patient attempted to recline on the right side. This circumstance, which I have now repeatedly observed in pyloric disease, is in all probability owing to the irritation produced by the gravitation of the fluid or food in the viscus against its diseased and necessarily morbidly irritable portions.

*Physical and chemical characters of the vomited fluids.*—During the whole course of this case, and in every variation of symptoms, the vomited fluid always presented the same general characters, being of a pale yellowish brown, never viscid or *filante* when freed from the mucus accompanying it, in which it differed essentially from the fluid of gastrorrhœa. It was invariably acid, often considerably so, and not unfrequently possessed a sourish odour, not unlike that of sour milk. Diffused through this fluid were almost constantly found a large quantity of minute yellowish granules of fat: these were

lenticular in form, and appeared quite independent of fatty matters taken into the stomach; indeed, so constantly were these present in all the cases I have examined, that I feel inclined to rank them among the peculiar secretions of this disease.

On freeing the vomited fluid from these sebaceous and mucous admixtures, by straining through a cloth, it very readily passed through filtering paper, and was then quite pellucid. It was remarkable how very rarely any debris of ingesta was met with in the fluid, even when vomited during, or antecedent to, the act of digestion: this fact tends to shew the probability of the opinion I have adopted of the gastric origin of many fluids which have been supposed to owe their origin to other sources, in consequence of the absence of ingesta\*. It is a curious circumstance that the fluids vomited in scirrhus pylorus are little liable to putrescence. I have repeatedly kept considerable portions in partially closed vessels for many weeks during the heat of summer, without their undergoing any change, save the separation into three layers, of which the lowest and densest consisted of mucous flocculi, and the lightest of sebaceous particles.

The table opposite gives at one view the chemical characters of the fluids vomited at six different periods in the case under consideration.

On looking at the results given in this table, we cannot help being struck by their general uniformity; no considerable difference existing between specimens of fluid vomited at different periods of the disease, and under different circumstances, whether voided spontaneously or under the stimulus of an emetic. In four specimens out of the six, ammonia was tolerably copiously evolved by the application of warmth after the addition of liquor potassæ; and this change was invariably accompanied by the deposition of brownish flocculi. All let fall a copious albuminous deposit on the application of a current of chlorine, as in other animal fluids poured out by mucous surfaces. The precipitate by nitrate of silver, which was always very copious and curd-like, dissolved readily in ammonia, and consisted nearly entirely of chloride of silver. The conversion of the blue

colour of a solution of sulphate of copper into green, on the addition of it to the fluid under consideration, is well marked, and depends upon its partial conversion into chloride of copper.

*Nature of the free acid present in the vomited fluids.*—We are unquestionably indebted to Dr. Prout for the positive demonstration of the hydrochloric acid in a free state in the gastric juice, and in certain specimens of fluid vomited in cases of irritative dyspepsia. This discovery, corroborated by the almost contemporary experiments of Professor Leopold Gmelin, and subsequently by the researches of many other chemists, have so fully demonstrated the accuracy of the observations of Dr. Prout, that no doubt can remain on the subject. It is true that objections have been adduced to the views adopted by this talented philosopher, chiefly on the ground that the hydrochloric acid supposed to have existed in a free and uncombined state, really was generated during the process of evaporation. This objection is, I am convinced from a careful review of the whole subject, totally untenable. It is supported at best by very forced analogy, and could only be entertained

for a moment by those who content themselves with taking a very partial view of the matter. I feel it is unnecessary to allude further to these hypotheses, than by remarking, that because a solution of chloride of sodium, when mixed with one of oxalic acid, and evaporated, evolves traces of free hydrochloric acid, it does not follow that the same thing would occur when the organic contents of the stomach are substituted for the oxalic acid. In no one case have I ever succeeded in obtaining indications of the evolution of hydrochloric acid when a solution of chloride of sodium is mixed with starch, mucus, and albumen, and submitted to distillation at a moderate temperature—as in a salt-water bath.

#### A. Examination of the fluid vomited on October 28th.

This fluid was deep-brown: it contained in suspension some mucous floculi, and was mixed with a small quantity of debris of food: it passed but slowly through paper, and then possessed the colour of pale ale.

1. Three fluid ounces of the filtered fluid were submitted to distillation in a vapour-bath, until two ounces had

passed over: the residue in the retort was evaporated carefully to as near dryness as the temperature employed would permit. A rich sepia brown, and very acid extract, weighing 67·5 grains, was obtained.

2. The extract thus obtained yielded to boiling alcohol of 0·845, nearly 19·4 grains, leaving the remainder in the form of a coagulated mass, which, however, dissolved in boiling water. The alcoholic solution yielded an acid extract, which was very fusible, evolved a strongly saccharine odour, and was capable of being readily drawn into threads.

3. The distilled fluid (1) was colourless, and possessed an odour of sour milk: it reddened litmus, but did not precipitate a solution of nitrate of silver. By repose, a minute fat-like pellicle formed on its surface. The two ounces of distilled fluid required eight drops of liquor potassæ for complete saturation.

4. An ounce of the distilled fluid (1) having been saturated by liquor potassæ, was carefully evaporated over a vapour bath to dryness. The residual mass was alkaline, and presented a greasy amorphous aspect. On the addition of a drop of strong sulphuric acid, a pungent odour, resembling that of acetic acid mixed with that of rancid butter, was evolved; violent effervescence accompanying this change. On the approximation of a rod dipped in hydrochloric acid, copious white fumes were given off.

5. Three fluid ounces of the filtered vomited fluid required exactly a drachm of liquor potassæ for its complete saturation.

6. A fluid ounce of the filtered vomited fluid was evaporated to dryness, the extract incinerated, and the ash boiled in dilute nitric acid. The filtered solution was mixed with one of nitrate of silver, and three grains of dry chloride of silver were obtained.

7. A fluid ounce of the fluid, neutralized by twenty minims of liquor potassæ, (5) was evaporated to dryness, ignited, and the ash similarly treated. The chloride of silver obtained weighed 5·1 grains.

The liquor potassæ used in this experiment was very pure. To determine the quantity of real alkali present, I supersaturated a fluid drachm with hydrochloric acid, evaporated the fluid

to dryness, and ignited the chloride of potassium thus obtained. It weighed exactly 5·4 grains: hence a fluid drachm of the solution of potass contained 3·416 grains of potassa.

From the above experiments we learn that the ash obtained from an ounce of the vomited fluid contained sufficient chlorine to yield three grains of chloride of silver. Here its hydrochloric acid existed uncombined, or combined only with a volatile base; in the fluid, it would be volatilized during the process of incineration; consequently the three grains of chloride of silver will point out the quantity of chlorine existing in the fluid combined with a fixed base. When previously neutralized with potass, the ash obtained yielded 5·1 grains of chloride of silver: this quantity will of course indicate the proportion of chlorine existing in the fluid in the form of hydrochloric acid, plus the quantity combined with a fixed base. Then, as 5·1 grains chloride silver are equal to 1·294 hydrochloric acid, and as 3 grains chloride silver are equal to 0·7614 hydrochloric acid, it follows that the quantity of free hydrochloric acid in an ounce of the fluid amounted to 0·5326 grains. Consequently, in every pint (3xx.) of vomited fluid there existed 15·228 of combined and of 10·652 grains of free hydrochloric acid. As the hydrochloric acid of the pharmacopœia, of specific gravity 1·16, contains 32·32 per cent. of real acid, it follows that every pint of the fluid vomited by this patient on October 28th, contained a quantity of hydrochloric acid equal to 32·9 grains of the pharmaceutical acid.

But in addition to the hydrochloric acid, there existed a volatile acid, consisting probably of a mixture of acetic and butyric (4) sufficient, in the fluid distilled from three ounces, to neutralize eight drops of liquor potassæ: consequently 3xx. of the vomited fluid contained, in addition to 10·652 of real hydrochloric acid, sufficient organic volatile acids to neutralize forty-three minims of liquor potassæ.

In this specimen of fluid, no ammonia was evolved on the addition of liquor potassæ; consequently no source of fallacy was present in the determination of the quantity of the hydrochloric acid by the presence of an ammoniacal hydrochlorate.

**B. Examination of the fluid vomited November 12.**

In its physical characters this fluid closely resembled that vomited on Oct. 28th. It was strained through flannel, and then filtered through paper.

1. One fluid ounce was distilled until five fluid drachms came away, the heat employed being that of a vapour-bath. The distilled fluid had a strong odour of sour whey, and its surface was covered with a thicker, glistening, fat-like pellicle, than in the former specimen. The extract left in the retort was much more acid than the original fluid, vividly turning crimson the deepest purple litmus paper.

2. The distilled fluid readily reddened litmus paper, but did not, in the faintest manner, affect the transparency of a solution of nitrate of silver.

3. Four fluid drachms of the vomited fluid were evaporated to dryness, and the extract carefully incinerated. The ash, dissolved in dilute nitric acid, yielded a precipitate of chloride of silver, weighing 1·8 grains on the addition of a solution of the nitrate.

4. Four fluid drachms of the fluid being carefully neutralized, and treated as in the last specimen (A. 7), yielded 2·5 grains of chloride of silver.

5. An ounce of the vomited fluid required fourteen minims of liquor potassæ for perfect saturation.

6. The addition of liquor potassæ, and the application of heat, did not cause the evolution of an appreciable ammoniacal vapour from the vomited fluid.

From these experiments it follows, that each ounce of this vomited fluid contained ·3554 grains of free hydrochloric acid, as calculated from the quantity of chloride of silver obtained from the ash of the neutralized fluid, minus that obtained from the ash of the un-neutralized fluid (3, 4). Hence, in each pint (3xx.) of the vomited fluid there existed 7·108 grains of real acid, equal to 22 grains of the hydrochloric acid of the Pharmacopœia.

The quantity of volatile acid can be calculated tolerably accurately from the quantity of liquor potassæ required to saturate the vomited fluid. Thus, 3xx. required 280 minims of liquor potassa for saturation (5), equal to 15·918 of potass; a quantity sufficient for the saturation of 11·72 grains of hydrochloric acid, or 4·612 grains more than

was really present. As 7·108 grains of acid require, for saturation, but 9·2 grains of potass, or 162 minims of the solution, it follows that as much of some acid destructible by heat as would neutralize 108 minims of liquor potassæ, or 6·7 grains of real alkali, must have co-existed with the hydrochloric acid.

**C. Fluid vomited November 17.**

In its physical characters it much resembled the two preceding specimens, being merely somewhat paler.

1. Submitted to distillation, it yielded an acid fluid precisely resembling that obtained from the other specimens. The extract left was very acid.

2. An ounce of the fluid required sixteen minims of the liquor potassæ for perfect saturation.

3. An ounce evaporated and incinerated, contained sufficient chlorine to yield 4·4 grains of chloride of silver.

4. An ounce previously saturated by potass, yielded, when treated as the other specimens (A B.), 4·6 grains of chloride of silver.

Then, as 4·4 grains of chloride of silver are equal to 1·116 hydrochloric acid, and 4·6 grains to 1·166, it follows that in each pint (3xx.) of the vomited fluid there existed—

Free and combined hydrochloric acid	23·320 gr.
Combined hydrochloric acid only	22·320

Leaving of the free acid only 1· gr.

As one grain of hydrochloric acid requires 1·3 grains of pure potass for saturation, and as the quantity of acid present in 3xx. of the vomited fluid was sufficient to neutralize nearly 3vss. of liquor potassæ, equal to about 18·2 of the pure alkali, it follows that a quantity of some acid, destructible by heat, sufficient to saturate 16·9 grains of pure potass, was present in the fluid.

In the determination of the quantity of free hydrochloric acid in this specimen, a source of fallacy exists in the presence of ammonia. For as the addition of liquor potassæ determined the evolution of the alkali, it is just probable that it existed combined with hydrochloric acid; and hence that part of the acid regarded as free (1 grain) may, in reality, have existed in the state of an ammoniacal salt.

[To be continued.]

## ON ALBUMINURIA.

*To the Editor of the Medical Gazette.*

SIR,

SHOULD you consider the following experiments and observations on albuminuria worthy of a place in your valuable journal, you will oblige me by inserting them at your earliest convenience.—I am, sir,

Your obedient servant,  
GEORGE ROBINSON, M.R.C.S.

Newcastle-on-Tyne, May 21, 1842.

In a memoir on the Pathology of Granular Disease of the Kidney, which I published at the commencement of the present year, I endeavoured to prove "that the acute stage of writers is simply acute nephritis, and that all the varieties of morbid appearances occurring in the chronic stage may be considered as resulting from so many different degrees in intensity and duration of chronic inflammation of the kidney."

Among other facts, I related in support of that view an experiment in which, by tying the renal vein of a rabbit, I produced a condition of the kidney precisely similar to that met with in acute nephritis. Since then, I understand that Dr. Stokes, in the Dublin Medical Journal for the month of March, has given the particulars of three cases which tend very much to increase the value of that experiment, and to corroborate the conclusions I drew from it. I regret that I have not at present access to that journal, but I believe that in two of those cases the renal veins were found inflamed; in the third this was not so apparent, but in all the coats were thickened so as to cause obstruction to the flow of blood, and in all albuminous urine had been secreted during life.

In connexion with that view of the pathology of the disease, I attempted to establish the following rule for the explanation of albuminuria:—"That the presence of albumen in the urine is produced by, and its proportional quantity is in a direct ratio to the degree of, congestion of the capillaries of the kidney, from whatsoever cause that congestion may arise."

In the above-mentioned experiment, the urine was not examined till fifteen

hours after the ligature of the vein, when it was found bloody. It therefore still remained for me to prove the truth of the rule by direct experiment, and this I have been enabled to do satisfactorily during a short stay in this town, where I have availed myself of the kind assistance of my friend, Mr. Fenwick, to whom I was indebted for much valuable advice in arranging my original views on the subject.

I subjoin the particulars of a few experiments, which I deemed it unnecessary to multiply further, as in them the proportion of albumen in the urine gradually increased, from the production of very minute flakes on the application of nitric acid and heat to the effusion of spontaneously coagulating albumen.

Exp. 1.—A young rabbit, not above six weeks old, the left kidney exposed, and its vein tied: the animal was killed ten minutes afterwards. The bladder was found distended with urine, which must have been chiefly secreted before the ligature was applied; tested with heat and nitric acid, permanent flakes were evident in the liquid.

Exp. 2.—A similar operation was performed on a rabbit of the same age and size, which was killed at the end of half an hour. A very small quantity of urine in the bladder; the same tests being applied, the flakiness was much more distinct than in the last experiment.

Exp. 3.—A larger rabbit used: the left kidney exposed and drawn out through the external incision, so that its vein was compressed for nearly ten minutes by the action of the surrounding muscles: the organ speedily and visibly enlarged, and presented the lividity of congestion. The vein was then separated from the artery, but in attempting to pass a thread under it the coats were slightly torn, and the blood immediately escaped from the distended vessels of the kidney, which at once fell to its natural size, and assumed its original colour. Compression was applied to the vein till the hæmorrhage ceased from the formation of a coagulum; the organ was then returned within the parietes of the abdomen, and the wound closed. At the end of half an hour the animal was killed, and about 3ij. of urine taken from the bladder: it was of the ordinary

colour of rabbit's urine, and contained the usual sediment. On allowing the latter to subside, and adding a few drops of nitric acid, there was immediate coagulation of the more liquid portion, whilst the sediment dissolved with effervescence: heat alone also coagulated the clearer part of the fluid; and this effect was still more manifest on the addition of a drop or two of nitric acid.

**Exp. 4.**—The renal vein of a similar rabbit tied tightly, so as completely to obstruct the return of blood from the kidney, which was then returned; and at the end of ten minutes the animal was killed. About a drachm of urine in the bladder, of a natural colour and appearance; and on adding to it a few drops of nitric acid immediate and decided coagulation took place, which was still further increased on applying a gentle heat. The kidney operated on was beautifully congested, the granular appearance of its surface being unusually distinct.

**Exp. 5.**—A strong full-grown buck rabbit. The renal vein exposed; but in clearing it from the fat previous to passing the thread round it, the coats were slightly lacerated, so that a little blood continued to ooze out by the side of the ligature. It was killed exactly an hour after the operation. A little urine escaped through the urethra, but on opening the bladder it was coagulated more firmly on exposure to the air. It was beautifully clear and pellucid, and could be compared to nothing so well as to a portion of the vitreous humour of the eye; in fact, presenting a perfect specimen of spontaneously coagulating albumen or lymph. It weighed rather more than a scruple.

**Exp. 6.**—A strong rabbit. The renal vein tied very loosely, and the ureter on the same side also ligatured. Killed eighteen hours afterwards. The kidney operated on gorged with blood: the urine found in the ureter above the ligature consisted chiefly of blood; that in the bladder was not albuminous.

In all these experiments the kidneys operated on were more or less congested; their colour darker, and their bulk and weight greater, than the remaining organs, which were, in every instance, perfectly healthy in colour, size, and structure.

It is evident that the degree of congestion of the vessels of the kidney

must depend upon, and vary with, the completeness of the obstruction to the return of venous blood on the one hand, and the intensity of the impulse given to the current of arterial blood, by the heart's action, on the other. Whenever the obstruction to the return of blood is incomplete, and the heart's action weak, then a low degree of congestion will occur; whilst, under opposite conditions, the effects of a more intense congestion will be found. The composition of the blood at the time, and more particularly its comparative richness in albumen, will also modify the nature of the effusion.

Bearing these principles in mind, it may be well briefly to notice each experiment in detail, for the purpose of explaining one or two apparent irregularities, which at first sight seem to affect the value of the rule.

In the first case the albumen, as it first entered the bladder, was diluted by the fluid already collected there; and this accounts for the small proportion found in the urine: but of course such a source of fallacy is not likely to occur in the human subject, and might be readily guarded against by frequently repeated examination of the urine. The rabbits used in the two first experiments were small and young, and not in good condition; and these circumstances taken together enable us to understand why the proportion of albumen in their urine was smaller than when a similar operation was practised for the same length of time on older and stronger animals. The loss of blood, by the wound in the renal vein, so far reduced the power of the heart's contraction in the third rabbit, that the proportion of albumen in the urine was not greater than in the fourth, although the latter lived about ten minutes after the ligature was applied, and the obstruction was continued in the former for more than half an hour; but here again the quantity of urine examined was much greater in one case than in the other.

In the fifth experiment every thing was favourable to the effusion of a highly albuminous fluid: the animal was strong and fat, its blood probably rich in albuminous matter, and by the accidental laceration of the coats of the vein, and the subsequent escape of blood by the side of the ligature, the congestion was maintained at the proper

degree for the exudation of the liquor sanguinis: whereas, if the obstruction had been in this case more complete, the probability is that the distension of the vessels would have been so extreme as to cause their rupture at some points, and the consequent extravasation of blood into the tissue of the gland, and also into the receptacle for the secretion, as happened in the sixth experiment. In this latter the only thing worthy of observation is, that the animal was alive at the end of eighteen hours; whilst in two former cases death took place within fifteen hours after the operation. The explanation of this difference in the results obtained appears to be that, in the present instance, a stronger and larger rabbit was employed, and that the ligature was more loosely tied than before.

I did not consider it necessary to repeat any more experiments on this head, as my present object is merely to prove the truth of the rule I laid down for the explanation of the presence of albumen in the urine, and to justify its practical explanation in determining at any time the intensity of the renal congestion, by ascertaining the chemical composition of the urine; so far at least as the presence and proportion of albumen are concerned. These experiments, taken in conjunction with the facts and arguments which I have elsewhere adduced, and supported as they are by the cases of Dr. Stokes, to which I have referred, seem to me to leave no room for doubting the correctness of that rule; and the ready and satisfactory explanation it affords of the *modus operandi* of the numerous and opposite causes to which albuminous urine has been traced by different observers, must tend to simplify the diagnosis of renal disease in general; at the same time that it presents a new method of ascertaining the condition of the circulation in the large venous trunks of the abdomen.

Before concluding, I must avail myself of this, the first opportunity I have since had, of expressing my thanks and acknowledgments to Dr. Bright for the kind and handsome manner in which, though personally unacquainted with me, he lent the weight of his name in support of views which might not otherwise have attracted much attention.

## ON ATMOSPHERIC PRESSURE UPON THE BRAIN.

*To the Editor of the Medical Gazette.*

SIR,

IN my communication to your journal of 6th May, I flattered myself that the fact of atmospheric pressure upon the brain was clearly established to the satisfaction of every body; but Mr. Bell's letter of 20th May convinces me to the contrary. Your correspondent so entirely misunderstands me, that I was ready to accuse myself of obscurity and confusion, and I submitted my paper to the perusal of a friend, not unknown to the scientific world, Mr. H. H. Watson, of this town. I was glad to find that he had no difficulty either in understanding it, or in admitting the principles it contained.

Let it be understood, that the question of atmospheric pressure upon the brain is a purely physical one; there is no vital law which can suspend or counteract this pressure; the consideration of it therefore must be kept quite distinct from the subject of circulation in the brain; but Mr. Bell has throughout mixed the two questions together. In the paper which Mr. B. endeavours to refute, the word *circulation* does not once occur; it is true it is headed "Circulation in the Brain," but that is not my doing, and is of no consequence. The meaning of a thing must not be looked for in the title, but in the substance. In considering the subject of the pressure of the atmosphere upon the brain, we may regard the vessels of the brain simply as tubes full of a fluid; it is quite immaterial whether that fluid is at rest or in motion.

I stated, that the head and its contents were in the position of an inverted long-necked globular vessel filled with water and any thing of the consistence of brain, clearly meaning *quoad* atmospheric pressure; Mr. Bell distinguishes this comparison with two notes of admiration. He then, unintentionally, no doubt, misrepresents me, by triumphantly inquiring, "what analogy can possibly exist between the circulation of the blood in the brain and a globular vessel filled with water turned upside down?" I leave those to answer the question who made the

comparison: I never made it. Mr. B. then expresses his astonishment that I should be so ignorant of the rules of reasoning as to pass off an illustration for an argument. Let it be taken as a mere illustration; it does ample duty as such, and throws light upon the reasoning in the previous paragraph in the paper under review. But it is more than a mere illustration, it is an example, and therefore an argument; it not only throws light, but also confirms. As far as atmospheric pressure is concerned, the abused inverted long-necked globular vessel, filled with water, is exactly in the same circumstance as the head with its vessels entering the cranium at the base of the skull; and what, in respect to this pressure, applies in one case, will apply in the other. We have, in the one case, the dome of the skull completely closed, there being no communication through it to the interior of the cranium, but at the base there are several vessels entering it containing a fluid. In the other case, we have the upper part of the globular vessel in the same circumstance as the upper part of the skull, and at the lower part we have a tube representing the veins and arteries, the vessel being filled with water, which it will retain, though inverted, if the experiment be performed with care. Now if the atmosphere presses upon the contents of this vessel through its neck, of which there is no doubt, so must it press upon the contents of the head through the medium of the blood-vessels. Mr. Bell says that if the vessels entered the skull at one point only, and if their *external* surface were subject to atmospheric pressure, my comparison might have some slight shade of plausibility. It is of no consequence to the comparison where the vessels enter, provided it be at the base of the skull: if the atmosphere acts upon one, it will act upon all, in the direction towards those parts of the inner surface of the cranium which are closed; and with regard to the supposed necessity that the atmospheric pressure should act upon the *external* surface of vessels, in order to produce any effect, it surprises me that there should be occasion to remind Mr. Bell that the atmosphere will press upon vessels whatever thickness of *soft* parts intervenes.

Supposing the comparison to be cor-

rect, Mr. Bell objects that too much would be proved; for in that case not a drop of blood could escape from the cranium, unless atmospheric pressure be admitted in an opposite direction. If Mr. Bell means that the quantity of blood in the brain could not be diminished, I agree with him; but if he means that no blood could return from the cranium by the veins, he is in error; for there is nothing to prevent as much blood escaping by the veins as enters by the arteries.

Complying with Mr. Bell's suggestion, I referred to Dr. Watson's valuable lectures, vol. xxvii. p. 741, of the *MEDICAL GAZETTE*. There I found a comparison *essentially* resembling the above, and in every respect similar to that drawn from the mode of sucking eggs. The Professor compares the head and its contents to a barrel of beer, of course, *quoad* atmospheric pressure. To quote from him. When Dr. Kellie trepanned a sheep, I found the brain as completely drained of red blood as any other part of the body; "he did that with respect to the blood contained in the brain which housekeepers do when they tap a barrel of beer. You know that if the barrel is quite full, you may introduce a faucet at its lower part, but no beer will run through it. The pressure of the atmosphere operates upon that portion only of the fluid which is now exposed to the air, and its effect is to keep the beer in. But if you bore a small hole with a gimlet through the top of the cask, and so admit air into the barrel, the beer will then flow readily through the lower outlet. Dr. Kellie imitated this process of making a vent-hole, when he trepanned the skull of the sheep, and admitted air to the yielding membranes of the brain." Dr. Watson certainly says in the same lecture that "the brain is exempt from atmospheric pressure;" but I presume this is from mere inadvertence, for his own comparison points out the contrary, and shows that it is owing to this very pressure that fluid can be drawn neither from the barrel nor from the head, unless Dr. Kellie's expedient be had recourse to, viz. making a vent-hole. The atmosphere as much presses upon the blood entering the skull, through the medium of the intervening soft parts, as it presses upon the fluid in the faucet of the barrel. Mr. Bell fa-

vours my comparison of the inverted vessels with two notes of admiration: as beer is more admirable than simple water, how many more would he bestow on Dr. Watson's? If it be true, as Mr. B. asserts, that I compare the circulation in the brain to an inverted vessel filled with water, or to an egg with an opening at one end only, it is equally true that Dr. Watson compares it to a beer-barrel. Perhaps your correspondent considers this latter comparison far more apt than the others, inasmuch as headaches are said to reside in barrels and hogsheads, and beer is sometimes heady.

I cannot understand the second paragraph of Mr. Bell's letter. He misrepresents me as saying that the pressure of the atmosphere operates from the centre of the brain towards its circumference; whereas the word "centre" does not occur in my paper. What I do say is this: "that the brain is so circumstanced that the direction of the pressure is from the outlets of the skull, giving passage to blood-vessels and nerves towards every part of the surface of the brain in contact with the dura-mater." In what direction does the air act upon the fluid in the faucit of a beer-barrel without a vent-hole, if not from the outlet, through the mass of beer, towards the inner surface of the barrel? In considering this question it is unnecessary to make any distinction between the veins and arteries which pass through the outlets of the skull, and I do not see on what ground Mr. B. makes the distinction.

The absurdity of atmospheric pressure upon the brain is proved, Mr. B. says, from the fact, that in the brains of executed criminals and strangled dogs there is not the slightest trace of congestion, while vessels on the outside are immoderately distended and even ruptured. I really do not see what strangulation has to do with the pressure of the atmosphere, either to increase or diminish it.

I am at a loss to know how Mr. Bell accounts for the fact, that blood will not flow from the interior of the cranium, so as to diminish the quantity of that fluid, when blood-letting is employed. Is it owing to the antique hatred that nature bears a vacuum, or is it that the blood is headstrong, and won't come out? Will not Mr. Bell confess that the inverted long-necked

vessel filled with water, the barrel of beer without a vent-hole, the egg with an opening at one end only, and the head with its vessels, are all in the same position, *quoad* atmospheric pressure?

Though not directly, yet by implication, Dr. Abercrombie assents to the fact that the brain undergoes the pressure of the air, as appears from a passage, page 302, 2d edition, of his work on Diseases of the Brain, where he says that the "brain is clearly shut up from atmospheric pressure, and free from all influence from without, except what is communicated through the blood-vessels which enter it." The above excellent authority, like Dr. Watson, inadvertently asserts that the brain is exempt from the pressure of the air, but afterwards admits it, when he says, "influence from without is communicated through blood-vessels which enter the brain."

At the risk of being charged with presumption, I venture to suggest to Mr. Bell the propriety of carefully studying the subjects of pneumatics and hydraulics; by so doing he will be convinced that no shut up cavity, which communicates with the exterior by any fluid or yielding substance, is exempt from the pressure of the air.

When I sent my first communication, which appeared in the MEDICAL GAZETTE of the 25th of February, on the "Effects of Shocks upon the Head," I had no suspicion that I was commencing a controversy involving the first and well-understood principles of natural philosophy; and I cannot but think it has been a loss of time and time to have entered so minutely into them. The necessity for so doing is to be regretted. One would almost think that Otto Von Guericke, and the illustrious Boyle, had lived in vain.

Mr. Bell has announced that, so far as he is concerned, the discussion is at an end. I am glad of it; for no doubt it has been wearisome not only to him and me, but to those who have accompanied us, if there be any. In accordance with a good old English custom, I shake hands with my antagonist, and take a friendly leave of him.

I am, sir,  
Your obedient servant,  
T. HAWORTH, M.D.

Bolton, May 28, 1842.

 publicum sit, dicendi periculum non recuso."

CICERO

EMPLOYMENT OF CHILDREN IN  
MINES.

"ONE half of the world," says Miss Edgeworth, "does not know how the other half lives:" a dictum confirmed by daily experience. If examples were wanting, we might cite the evidence furnished by a report just published\*. It appears that in 1840 a commission was appointed, in pursuance of an address from the House of Commons, to inquire into the condition of the children employed in mines, and various trades not included in the provisions of the Factory Act. The Commissioners thought themselves bound to construe the term children in the sense assigned to it in the act just mentioned, where it is limited to those under thirteen years of age; but in compliance with another address of the House, their powers were enlarged, and the inquiry was extended to young persons, *i. e.* those between the ages of thirteen and eighteen. The Commissioners were Dr. Southwood Smith, Messrs. T. Tooke, Leonard Horner, and R. J. Saunders, assisted by a number of sub-commissioners. The facts brought out in this portion of their inquiries are singular indeed. Had it been possible to anticipate the existence of the scenes described anywhere, we might have imagined them among the convicts of Australia, or the apprentices to the Dutch boors at the Cape of Good Hope; not in this country, which has so many

just claims to be considered the very leader of civilization. But there are spots in the sun.

The first point considered in the Report is the age at which children are first employed in coal mines. The most usual age appears to be eight or nine, but they often begin much younger, and sometimes at four or five. The custom in this respect varies in different parts of the kingdom. Thus in the pottery district of North Staffordshire, the employment of children in the potteries prevents their being taken into the coal mines under thirteen years of age; while in the Coalbrook Dale district in Shropshire, some children begin to work in the pits at six. Nay, Dr. Mitchell, one of the sub-commissioners, found an instance where a child a little more than four was regularly taken into the pit by his father.

In the collieries of the East of Scotland this early commencement of work is still more common than in any part of England. The manager of the Fordel Colliery, the property of Admiral Sir P. Durham, Bart. of Fordel, says: "We have 82 young persons and children working below ground. The females begin to assist to draw by the chain from six years of age, and many from six to twelve years of age are employed." These children, too, are often employed in hard, oppressive work: thus Margaret Leveston, a coal-bearer, six years old, says—"Been down at coal-carrying six weeks; makes 10 to 14 rakes a day; carries full 56 lbs. of coal in a wooden bucket. The work is na guid; it is so very sair."

In South Wales and Monmouthshire matters are still worse, as it is no very unusual thing in this district for children to be taken into the pits as early as four years of age. A witness who is under-agent to Gellgan collieries, says: "Children are taken down as soon as they can crawl."

\* Children's Employment Commission. First Report of the Commissioners. Mines. Presented to both Houses of Parliament by command of Her Majesty. 1842.

But it is the next point discussed, entitled "Sex: Employment of Girls and Women in coal mines," which is the darkest chapter in the Report. If the promiscuous assemblage of girls and boys in the factory and the workshop has always been unfavourable to morals; if, even there, modesty is soon exchanged for boldness, and effrontery deepens into vice; what can we expect from mines like those of Yorkshire, where men and girls work together, the former quite undressed, the latter nearly so, but the orgies of a brothel?

Mr. George Armitage says, "I hardly know how to reprobate the practice sufficiently, of girls working in pits; nothing can be worse. I have no doubt that debauchery is carried on, for which there is every opportunity; for the girls go constantly, when hurrying, to the men, who work often alone in the bank-faces apart from every one. I think it scarcely possible for girls to remain modest who are in pits, regularly mixing with such company, and hearing such language as they do." Joseph Ellison, of Birkinshaw, near Birstall, says: "I know a case of a girl being employed as a hurrier, having been attempted to be ravished frequently by her father-in-law, till at length she could not be got down into the pit. Where girls are employed, the immoralities practised are scandalous."

"I consider it a scandal," says another witness, a woman, "for girls to work in the pits. I am credibly informed that in some pits scenes pass which are as bad as any house of ill-fame: this I have heard from young men who work in the pit."

But perhaps the best proof of the badness of the system is to be found in the following resolution, passed at a meeting of colliers held before the sub-commissioner at Barnsley, in Yorkshire:—"That the employment of girls in pits is highly injurious to their

morals, that it is not proper for females and that it is a scandalous practice." Among more than 350 working colliers present, there were only five dissentient voices. This is very strong evidence indeed; for the probability that some were influenced in their votes by the presence of the sub-commissioner is far outweighed by the apprehension which they must have felt of immediate loss through a change in the system.

Independently of this depravity, the toilsome life of these women is morally degrading. Out-of-door work, in general, has an unfavourable influence on the feelings as well as the constitution of women. The withered features of the female day-labourers on the Continent indicate how little their employment is suited to their sex; and the domestic charities can scarcely flourish when she who should foster them is withdrawn from the home where they should spring up.

In the West Riding of Yorkshire this wretched system is at its height. According to one of the sub-commissioners,

"Girls regularly perform all the various offices of trapping, hurrying, filling, riddling, tipping, and occasionally getting, just as they are performed by boys. One of the most disgusting sights I have ever seen was that of young females, dressed like boys in trousers, crawling on all fours, with belts round their waists, and chains passing between their legs, at day pits at Hunshelf Bank, and in many small pits near Holmfrith and New Mills: it exists, also, in several other places."

In other districts, as in Lancashire and Cheshire, the same practice prevails. Thus Betty Harris, aged 37, drawer in a coal-pit at Little Bolton, says:—

"I have a belt round my waist, and a chain passing between my legs, and I go on my hands and feet. The road is very steep, and we have to hold by a

rope, and when there is no rope, by any thing we can catch hold of. There are six women and about six boys and girls in the pit I work in: it is very hard work for a woman. The pit is very wet where I work, and the water comes over our clog-tops always, and I have seen it up to my thighs; it rains in at the roof terribly; my clothes are wet through almost all day long. I never was ill in my life, but when I was lying-in. My cousin looks after my children in the day-time. I am very tired when I get home at night; I fall asleep sometimes before I get washed. I am not so strong as I was, and cannot stand my work so well as I used to do. I have drawn till I have had the skin off me; the belt and chain is worse when we are in the family-way. My feller [husband] has beaten me many a time for not being ready. I were not used to it at first, and he had little patience; I have known many a man beat his drawer."

A similar practice prevails in the East of Scotland. The women have to crawl backwards and forwards with small carts in seams often not more than 22 to 28 inches high. The labour lasts from twelve to fourteen hours daily. One girl, aged ten, deposes that she carries loads weighing a cwt.; another, of seventeen, works at night the alternate weeks; she then goes down at 2 P.M., and comes up at 4 or 6 A.M.

Jane Peacock Watson says, "It is only horse-work, and ruins the women; it crushes their haunches, bends their ankles, and makes them old women at forty."

Here, as well as in England, the custom of working till the last moment of pregnancy appears to be a frequent cause of miscarriage.

In many large coal-districts neither women nor girls are employed under ground; for instance, in Staffordshire, Shropshire, Durham, Northumberland, South Gloucestershire, and Ireland. In Cumberland, the practice occurs only in one old colliery belonging to

the Earl of Lonsdale; and in the West of Scotland, though not absolutely unknown, it is extremely rare. In South Staffordshire, many women are employed under the name of bankswomen, not to work in the pits, but above ground, to unload the *ships* as they come up.

It is pleasant to add that a reform has been effected in some places where the old system once prevailed. Thus women and girls have been excluded for some time from the Dalkeith collieries by the express command of the Duke of Buccleugh; and, for the last four years, from those belonging to Mr. Ramsay. According to the managers of his Grace's coal-mines, as well as Mr. Ramsay's, when women are employed as coal-bearers, they are often selected as wives, for their strength, rather than from affection, or for their domestic qualities.

In the Arniston Colliery, women are not allowed to go below at all, and no boys under twelve years of age. These rules have been established there for some time past, and, according to Mr. A. Maxton, the manager, with the best effects. The houses of the workmen are clean and comfortable; the mothers attend to the children, and the young women go out to service.

The colliers, too, are sensible of the benefit thus conferred on them; and although many men and families left, when the order was first issued, many have now returned; for the roads having been improved, and the *output* not limited, they find they can earn as much money, with the addition of a comfortable home.

Such are a few of the points touched on in this Report: to discuss them all would far surpass the limits of a single article.

## BIOGRAPHICAL SKETCH

OF THE LATE

SIR CHARLES BELL, K.H. F.R.S. &amp;c.

THIS eminent surgeon and physiologist, whose recent death has deprived the profession of one of its brightest ornaments, was the youngest son of the Rev. William Bell, a clergyman of the Episcopal Church of Scotland.

He was born in the year 1775, and received his education in the High School of Edinburgh. He was still very young when he began the study of anatomy under the celebrated John Bell, who, twelve years senior to his brother Charles, was already in the highest estimation as a lecturer and a surgeon, and to whom he was apprenticed in 1792.

To the instruction he received under this enthusiastic and highly gifted teacher, may, in great measure, be attributed the success with which Mr. Bell cultivated and improved the sciences of anatomy and physiology; and the ardour with which he at this time pursued his studies, is shewn in the publication of the first volume of his "System of Dissections," when he was yet only in his twenty-second year. This, his earliest work, bears that stamp of originality which characterized every production of his after-life. It presents the germs of numerous important doctrines which he employed himself in developing in his later publications. The engravings contained in it, taken from original drawings by himself, with some etchings by his own hand, prove how accomplished he was as an artist at that time; and were the first indications of a power of using his pencil, which was not only useful for illustrating his lectures and works, but was the source to him in private life of never-failing pleasure.

In the year 1799, Mr. Bell became a Fellow of the Royal College of Surgeons of Edinburgh, and was shortly afterwards appointed Surgeon to the Royal Infirmary. Here he soon acquired reputation as an operator, by his simple and dexterous manner of using the scalpel alone in the operation of lithotomy. A few years afterwards he determined to relinquish his prospects in Edinburgh, and seek success in London. To this step he was led by many circumstances, amongst the principal of which was,

perhaps, the excited state of party feeling at that time existing in Edinburgh, and from the annoyances of which he could scarcely hope to escape, as his brother, whose powers of sarcasm and peculiar aptness for controversial writing made him an object of fear and dislike to his opponents, was at this time leader of one of the parties which divided the profession.

Mr. Bell came to London in 1806, and very soon gained for himself a high reputation as a lecturer on anatomy and surgery. Nothing can more decidedly prove how great were his qualifications for the career on which he had embarked than his success at such a time. Unsupported—dependent on his own exertions alone—he was enabled to enter into competition with Cline, Abernethy, Cooper, and others scarcely less known, and to come off with honour. Himself an ardent lover of his profession, he had a manner, scarcely to be surpassed, of inspiring in others the same admiration, and he could invest with an interest before unfelt the driest details of anatomical demonstration.

It was only to be expected, that, with these powers, combined with an unwearying devotion to his professional pursuits, and to the progress of his pupils, he should have been enabled—associated with Mr. Wilson, and afterwards with Mr. John Shaw, in the school of Great Windmill Street—to raise the character of that school to the highest pitch. His lectures could not fail to interest and instruct even those who were unable to appreciate that boldness of conception and originality of mind which were displayed in them, and which afterwards led to so great results. It was in this school that he first explained his original and beautiful views on the Nervous System—those views which have gained to himself immortality, and reflected honour on his country.

Mr. Bell's fame as a surgeon must at this time have stood very high in London; for, in 1812, he was elected surgeon to the Middlesex Hospital, after the severest contest ever known in that institution. From this time, till he quitted London, he lost no opportunity of giving clinical instruction to the pupils. Many of these lectures were published in this journal: and our readers will not think that we ex-

ceed in our praise, if we represent them as among the best models of that style of teaching to be found in medical literature.

Previous to his election, he had received, after a nominal examination, the diploma of the College of Surgeons of London.

His zeal in the cultivation of professional knowledge had been before, and it was subsequently, instanced by the alacrity with which he availed himself of the opportunities offered for the study of gun-shot wounds by the battle of Corunna, and afterwards by that of Waterloo. After the latter action, he and his brother-in-law, Mr. John Shaw, were the first surgeons from England who arrived at Brussels; and Mr. Bell was unremittingly employed in his attentions to the wounded, in taking cases, and in making those sketches and drawings which have been justly regarded as amongst the finest specimens of water-colour painting. For three successive days and nights was he engaged in operating on and dressing the wounded, and he had no fewer than 300 cases under his own personal care. The results of his observations are appended to his "System of Operative Surgery."

His appointment to the Professorship of Anatomy and Surgery to the College of Surgeons, a few years later, gave him an opportunity of displaying, in the most decisive manner, the depth and clearness of his reasoning powers, the originality of his mind, and his singularly felicitous method of imparting knowledge.

He chose for his subject, among others, one which was always a favourite with him, "The evidence of design in the formation of our frames;" and he was daily listened to with attention and delight by crowds of the most eminent men of the day both in and out of the profession. That his style combined a substantial and effective power of reasoning which satisfied the understanding, with an easy and impressive manner that bound his listeners' attention to him, may be illustrated by a saying imputed to the present venerable Bishop of Durham, then a frequent attendant upon his lectures—"Sir Charles Bell's discourses convey to me the impression not so much of a lecture, as of a man *thinking aloud*."

To the delivery of these lectures we

owe the publication of his two papers on "Animal Mechanics" in the Library for the Diffusion of Useful Knowledge, in which is illustrated, in his most happy manner, the idea, that the type of most of those mechanical contrivances which the labour and ingenuity of man have been so long in perfecting, may be found by the inquirer in the construction and adaptation of parts in the animal economy. The remarkably extensive circulation of these papers proves how favourably they were received by the public.

Following out the same train of thought, he was led, when selected by the trustees of the Earl of Bridgewater to write one of the treatises in fulfilment of the wishes of that nobleman, to choose the subject of the "Hand"; his essay on which is too well known and appreciated to need comment.

He was afterwards associated with Lord Brougham in the publication of the illustrated edition of "Paley's Evidences of Natural Theology"—a beautiful work, to which both his pen and pencil contributed largely.

His reputation as a man of science, in consequence of these publications and his physiological discoveries, rose so high, that on the accession of William IV. he was amongst the number of those who received the honour of knighthood as an acknowledgment of their high scientific merit. In the meantime, he continued with undiminished success to deliver his lectures in Great Windmill Street, until the year 1828, when he was induced, on the formation of the London University, to accept the chairs of Physiology and Surgery in that school; and to him it was allotted to give the first lecture delivered within its walls.

He did not long remain attached to this institution, the dissensions which arose soon after its establishment causing him to relinquish his Professorship. His connection with the Middlesex Hospital, however, continued, until his appointment to the Chair of Surgery in the University of Edinburgh, in 1836, induced him to leave London, and to return to the scene of his early labours and his early success; taking with him the regrets of all who knew him, and the respect and esteem of the whole profession.

The life of Sir Charles Bell was one of incessant and laborious study. This is sufficiently evidenced by his

numerous works. Few, however, except his friends, know how unremitting was his application to his duties as a Teacher—with what care and attention each lecture, though only clinical, was studied, even to his last course.

His earliest publication was his "System of Dissections," in folio. He next took part with his brother in that excellent, and we may say unrivalled work, "The System of Anatomy," which passed through seven editions; and, within a few years after, he had published, at successive times, his Engravings of the Arteries, of the Brain, and of the Nerves.

These were soon followed by his essay on the "Anatomy of Expression," one of the most elegant works in our language, and which is esteemed one of the greatest gifts conferred by anatomy on the arts. A third edition of this work, enriched with observations made by him while on a tour in Italy two years ago, has been left, we understand, ready for the press.

"The System of Operative Surgery" appeared in 1807. The brilliant and undying fame which Sir Charles Bell has acquired as a physiologist has perhaps been prejudicial to his reputation as a surgeon; but for matters appertaining more immediately to surgical practice, the profession are not less his debtors than for his general physiological researches and discoveries. Sir Charles was ever employed in directing his powerful and vigorous mind towards points of daily practice. We have seen, in his desire to improve himself in the study of gun-shot wounds, how regardless he was of labour and personal inconvenience. The same zeal was ever at work in him. But with those powers of generalization which he possessed to so large a degree, his attention was always directed to the elucidation of general principles. Hence his surgical writings do not appear to possess at first view that practical character which is so satisfactory to the mind of the student. The views contained in them are not, however, the less practical; and they have this additional advantage, that all the precepts they contain flow from and are supported by close reasoning, founded on an extensive range of observations. "The System of Operative Surgery" is a work purely practical. Every step of an operation, from the preparation to the final dressing, is described; and

it may not be too much to say that, amidst all the improvements and alterations which have taken place in practice since its publication, there is no work more calculated to be of real service in this department of surgery.

Sir Charles was in every way eminently gifted as an operating surgeon. His extensive knowledge of anatomy, the instructions he received under his celebrated brother, who ranked so high as a practical surgeon, the remarkable accordance of his eye and hand, his entire self-confidence, all combined to render him one of the first operators of his day. But it is perhaps more to his praise, that he never allowed himself for a moment to forget the safety or welfare of his patient in the desire to make a display; and he was backward, even to a fault, in risking an operation. The results of his experience, clothed in his own simple but forcible language, are contained in his "System," and will never fail to be a sure guide to the surgeon.

His after surgical publications were his letters on the Diseases of the Urethra, published in 1809, of which a new edition in an enlarged and improved form was brought out by Mr. John Shaw in 1820: the Engravings from specimens of Morbid Parts contained in the Windmill Street Museum, in 1813; and his Surgical Observations; the first number of which appeared in 1816, and the last in 1818. Then followed the Illustrations of the Great Operations of Surgery in 1821, and the Observations on Injuries of the Spine and Thigh-bone in 1824. Soon after this he published an octavo edition of John Bell's Principles of Surgery.

After he quitted London, he published in 1837 his "Institutes of Surgery," which were intended as a sort of textbook to his course of lectures in the University of Edinburgh; and his last work was his "Practical Essays," the first volume of which appeared in 1841, and the second in 1842.

Besides these there are many anatomical and surgical papers in the Medico-Chirurgical Transactions, one of which, "On the varieties of diseases comprehended under the name of Carcinoma Mammæ," contains the results of his observations made in the cancer ward of the Middlesex Hospital.

In connection with physiology the name of Bell will go down to posterity side by side with that of Harvey and

of Hunter; principally associated with his important and brilliant discoveries on the functions of the nervous system. It would be impossible here to go into any account of these views, and they are now known throughout the world. Let it be remembered, in regard to them, that the value of his observations is not to be calculated solely by the importance of the facts ascertained concerning the nerves themselves; but that a new direction has been given to the current of physiological inquiry by the investigations, and vast improvements have been introduced in our knowledge of the functions of the various organs of the body generally, while seeking to elucidate the uses of the nerves distributed to them. His views on the subjects were first propounded in his lectures in Great Windmill Street, and in a small essay written in 1811, entitled "Idea of a new anatomy of the brain." But it was in the papers of the Royal Societies of London and Edinburgh, begun in 1821, and continued till the period of his decease, that his opinions were fully discussed. In acknowledgment of the merit of these splendid discoveries, the gold medal of the Royal Society was awarded to Sir Charles Bell in 1829.

The matter contained in these papers has since been published in separate volumes, at different times.

The only other physiological work, besides those already named, was "An Essay on the Forces which circulate the Blood," in 1819; containing some singular and ingenious views on that subject, in opposition to the mechanical doctrines of the day.

Before concluding this short sketch of one who for nearly half a century devoted his high talents to the advancement of our profession, it may be expected that we should say a few words on his private deportment in social life. His manners, we would say, were characterized by unpretending simplicity, combined with an openness and cheerfulness of demeanour, the best signs of an honourable and self-respecting mind. Refined in his tastes—blending in his manner great courtesy, with a dignity which commanded respect—his conversation flowing easily and naturally from the sources of his richly-stored and fertile mind, aided by his retentive and ready

memory, and heightened by a vein of true and refined wit—he was in every way calculated to be an ornament to society.

With his singleness of character were united great firmness and moral courage: the fear of consequences never deterred him from inflexibly following what he considered his duty; his energy of mind often drew him into a forgetfulness of every object foreign to that which was occupying him; of what the world would have considered his interests he was never careful. Hence he was often regarded by those who did not know him as cold, indifferent, and severe; persons who really knew him will never cease to remember how entirely the reverse was his true disposition. He had a warmth of feeling which made him ever keenly alive to the happiness or misfortunes of his friends; ever ready to afford them his advice and assistance, and to promote their welfare to the utmost of his power.

Constantly exercising, even in relaxation, his acute powers of observation and natural ingenuity, objects to occupy and interest him were seldom wanting. Indeed he displayed, in a remarkable manner, an enlightened sympathy with every, even the meanest, work of nature. From this cause it may have arisen that his pleasures and solacements from the toils of business were usually obtained from simple sources. One principal feature of his character was his being an ardent admirer of the beauties of the country, to which no doubt his facility and admirable skill in sketching from nature greatly contributed. For many of his latter years he was a keen fisher, a sport the love of which was partly cherished on account of the healthful exercise it secured to him; but more, perhaps, for the delightful rural scenes into which it carried him. In fine, we may sum up his private character by saying, that, joined to his highly philosophical and powerful intellect, he possessed a heart warm and generous, and susceptible of the kindest impressions. Gifted with qualities to command admiration in others, it was the affection of those immediately around him, and connected with him by long friendship, for which he seemed principally to live.

[For the particulars connected with the decease of Sir Charles Bell we refer to our No. for May 6.]

# ROYAL MEDICAL & CHIRURGICAL SOCIETY.

THE PRESIDENT IN THE CHAIR.

May 24, 1842.

*On the separate and combined Actions of the Muscles of the Eye and its Appendages.* By EDWARD HOCKEN, M.D.

The object of the author in this paper was to consider the physiology of the obliqui, recti orbicularis palpebrarum, levator palpebræ ciliares, and tensor tarsi, both separately and in combination. This he does considerably in detail, illustrating his observations by reference to the phenomena of strabismus. The novelty of the facts and arguments adduced by the author, however, seemed to us not quite so evident, as their intrinsic value was admitted and unquestionable.

*Cases of Malformation of the Heart.* By BELL FLETCHER, M.D., Physician to the General Dispensary, Birmingham.

The first of these was one of aneurism and dilatation of the pulmonary artery, with malformation of the heart and arteries.

The patient was a young woman, æt. 19, who, with the exception of slight cough, had enjoyed good health up to the age of 16; since that time she has had frequent attacks of pain in the chest, cough, and dyspnoea. She was first seen by the author in August 1839, when she had cough and dyspnoea, with slight hæmoptysis. On the left side of the sternum, between the second and third ribs, there was a superficial pulsation, with purring tremor, and a loud rasping souffle; the impulse of the heart was normal. She recovered under the use of remedies employed, but had several similar attacks between that time and Dec. 1840, when she had severe inflammation of the lungs. At this time, the pulsation of the chest mentioned above was more extensive, the souffle louder, and it had assumed a seesaw character, masking the sounds of the heart. The patient lingered for some time, and though relieved by treatment, died rather suddenly on May 1st.

*Examination after death.*—Our account of the appearances must be confined to the state of the heart and great vessels. The heart was about twice its natural size; its parietes of the natural thickness, the dilatation being equal in all their cavities. The right auricle, excepting the dilatation and hypertrophy, perfectly normal; the tricuspid valves healthy. The auriculo-ventricular opening is dilated, so as to render the valves somewhat ineffective. In the right ventricle the columnæ carneæ are thicker than normal:

the orifice of communication with the pulmonary artery is much dilated. Immediately below the opening is a communication with the left ventricle, which measured about one-third of an inch across, and one-eighth from above downwards. The two anterior semilunar valves are perfect, of the normal size, but much thickened; the posterior one imperfect, being so narrow and constricted in its middle portions, as to be a mere band-like projection from the artery.

The pulmonary artery is much dilated, being five inches and three quarters in its greatest circumference (internal measure); the branches of the pulmonary artery are much dilated. The left auricle is healthy, save the dilatation and hypertrophy; the auriculo-ventricular opening is dilated; the mitral valve is normal in structure, but not sufficient to close the dilated opening perfectly.

In the left ventricle the columnæ carneæ are thicker than usual; and at the base of the cavity is seen the opening of communication with the right ventricle.

The opening of the aorta is rather dilated: semilunar valves healthy. The ascending aorta is dilated about one half beyond its natural size. The distribution of the arteries from its arch may be considered more as divisions of the artery than branches. After giving off these, it is contracted to about one-third of its capacity in the ascending portion; and the coats of the vessel are thinned in this situation. This contraction extends from the root of the left subclavian to the adjoining with the ductus arteriosus, where the artery is still further contracted by a hardened thickening of the coats, projecting into its anterior, so as to contract the capacity again to be one-third; so that at this point the capacity of the artery is not more than one-ninth of its ascending portion. Just on the distal side of the constriction is the communication with the ductus arteriosus, and immediately below it the artery is dilated to the usual size of the descending aorta.

The second case was one of cyanosis; the subject of it a young man, aged 21. He had great dyspnoea, palpitations, anasarca, and a blue state of the skin generally. The heat of the body in the axillæ or mouth was not more than 80° of Fahrenheit: the state of puberty was not developed. The impulse of the heart was greater than normal. There was a *bruit de soufflet*, beginning with the first sound of the heart, sufficiently long to mask the second: it was heard most distinctly under the middle bone of the sternum.

*Examination after death.*—The heart and large veins enormously distended with dark-coloured blood. The organ much enlarged and hypertrophied. The septum of the

auricles so totally absent as to convert the two into one.

The veins of the general circulation enter it on the right side of a line drawn in the situation of where the septum should be, and the pulmonary veins on the left of it. The auriculo-ventricular openings are large, and between them the septum of the ventricles is much notched out. The orifice of the aorta is contracted to a third of its usual capacity, and its semilunar valves are diseased and ineffective.

The liver much congested, and enlarged about a third more than its usual size.

The Society then adjourned to the 14th June.

### MEDICAL CHARITIES' BILL.

At the anniversary meeting of the Irish Medical Association, recently held, the following resolutions were passed expressive of the opinion entertained by the members of the Medical Charities' Bill for Ireland:—

“That we have learned that the proposed Medical Charities' Bill was drawn up and printed without the knowledge of the Attorney or Solicitor General or Under-Secretary for Ireland; that it was pressed upon the notice of Lord Eliot under misrepresentations, that nobleman having been incorrectly informed by Mr. Nicholls, the Chief Poor Law Commissioner, that its provisions had been made known to and approved of by certain eminent medical practitioners in Dublin; that some of these gentlemen denied the truth of Mr. Nicholls's statements, in his own presence and before Lord Eliot; that we therefore consider him unfit to give any opinion as to the management of interests so important as those of the medical charities in Ireland.

“That it is our opinion that the report and supplemental report upon the medical Charities in Ireland, published by the Poor Law Commissioners, contain many unfounded statements; that the truth has been in many instances suppressed in these publications; and that they do not, therefore, furnish safe and sufficient information whereon to found any legislative measure.”

### SIR R. CHERMSIDE.

This gentleman, who has long been resident in Paris, where he enjoys extensive practice, has just been nominated a Knight of the Legion of Honour, by his Majesty the King of the French.

### MACCLESFIELD MEDICAL AID SOCIETY.

*To the Editor of the Medical Gazette.*

SIR,

I HAVE just seen in your number of the 20th inst. a letter, dated May 2d, from one who signs himself “A Constant Reader and Subscriber,” in which my name appears in connection with a society which was formed here about six months ago. About four months since, a letter, which I have every reason to believe emanated from the same source, appeared in the *Lancet*, to which publication, and not to your journal, I strongly suspect the author of them is a “Subscriber.” Of the purport of this I was only made acquainted by a medical friend here; the *Lancet* being a work which I have not opened half a dozen times in my life. I treated this with the silent contempt which I feel alike for the author and his veracious productions. Since, however, a letter has appeared in your journal, and devoid of those scurrilous editorial remarks which characterized the former, I think it but just to myself that I should give you more correct history than that furnished by your correspondent; putting you in possession of facts in connection with it which he was not sufficiently ingenuous to inform you of; correcting those statements which are wilfully misrepresented; denying others which are totally false, and thus placing my professional character and conduct in a different light to that in which he would make it appear by a perusal of his letter.

No one can have a greater abhorrence than myself of the truly despicable system of medical contracts—from the poor Union doctor, receiving his sixpence or shilling a head, to the practitioner of a large town with his ten or twenty pounds for a family. The system of contracts for clubs is one which prevails, to a great extent, here; and to the effects produced by these may be mainly, if not entirely, attributed the departure from that Utopian state which your correspondent would have us believe formerly existed, but which, if it ever did exist in reality, must, I should opine, have certainly been prior to his establishment here. The name of club doctor here is coeval with the introduction of a junior practitioner a few years since—several years before the formation of the obnoxious society; which can be clearly proved to be an emanation from, and extension of, the club contract system. Now what has been the effect of these clubs? An old-established, respectable, and respected practitioner here, and who had a very good country practice amongst the farmers, in-

formed me (before the society had existence) that all these people were now attended by the club doctor, and that he had, in consequence, ceased to keep a horse, not having employment for one.

Perhaps it is not known that societies similar to this exist in most, if not all, the small towns in the manufacturing districts of Cheshire and Lancashire. The one here, however, originated with a lodge of Odd Fellows, who, seeing the principle recognized and acted upon, so far as regarded the members themselves, considered that the same might be carried out so as to include their families; many being afterwards admitted who were not members of the lodge. It is necessary for me to mention this, in order to disprove the statement of your correspondent, which would make it appear that I was the only one who would accept of the office. This, however, he is as well aware as myself is quite at variance with facts which I shall presently disclose. With the origin and formation of the society I had nothing to do. Until I was waited upon by several persons about the end of last November, and requested to undertake it, I was not even aware of its existence. Not so, however, another practitioner, of much longer standing than myself, and with an extensive and respectable practice: a fortnight before it was offered to me he offered his services to them, which were, however, declined. He could not plead ignorance of the nature of the office which he sought: his informant, from having attended the meetings, was able to give him the fullest information. I hesitated at first to accept the office, requesting a few days for consideration; after which, and consulting some friends, medical and non-medical, I consented. I had two motives for this: to prevent my patients being clandestinely obtained through the medium of the clubs; and not without a hope that it might possibly be the means of doing away with this system altogether.

Of the publication of the placard I knew nothing until one was put into my hands by the printer, and my name was attached without my consent, or even knowledge. Had I known that any thing of the kind was in contemplation, I should have strongly reprobated it. A few days prior to the Society's commencing operations, a meeting of the medical men was called to discountenance the affair, and to prevail upon me to have no connection with it; and the man who was loudest in his condemnation of it, and who most strongly expressed his determination to have no connection with any thing of the kind, was the one whose previously proffered services had been declined.

A copy of his note, which was read at the

meeting, I now subjoin, having the original still in my possession:—

"Gentlemen, — Understanding that you are thinking of appointing a medical officer to your Lodge\*, I beg to offer my services in that capacity, and to say that in case you think proper to elect me, my best energies shall be devoted to your service.

"I am, gentlemen,

"Your obedient servant,

—"

On this being read, he stated that the step had been sanctioned by a practitioner then present; to whom he referred for confirmation of this. I consented to give up my office as soon as I consistently could, conditionally that the club system should be entirely abandoned; an agreement to which effect was drawn up, and signed by all present. In accordance with this I resigned my office some weeks since; but as yet no disposition has been shown on the part of others to follow my example.

The remuneration from the society was much greater than that from the clubs. The latter pay from one shilling and ninepence to two shillings each in the town, and, I believe, half a crown in the country. From this, however, has to be deducted the subscription as a member of the club, which, when the club is small, would perhaps, where he received one shilling and ninepence, leave him on an average one shilling and threepence each. In the society the sum paid was two shillings and twopence each, besides extra subscriptions, entrance, &c. which would approach three shillings. From the latter fund I was to receive extra payment for surgical cases and injuries of a severe character. One of the clubs is six miles, at least, from this place; and the Doctor might have to go eight miles to see a patient.

In denying the truth of the other statements contained in the letter I shall be brief. Before I attended a single case of midwifery, it was arranged that for this I should receive extra payment. I attended two cases; an assistant, for the sake of practice, attended a few more. This arrangement for payment was at no subsequent period altered. So much for the assertion that I attended labours gratuitously! There were very few members in the country, and none were admitted, beyond the limits of the town, after January; after the first of which month no canvass took place for members. With reference to the class of people who were members, if such as these constituted his practice, then indeed would his pocket be

\* This is the Lodge above alluded to.

affected; his condition would be truly pitiable.

I would remark that the letter is dated a fortnight after I had given up my office, and published nearly five weeks after. That I had done so was known to all the medical men here before the date of the letter. Your correspondent is an anonymous one. Were his letter written for the purpose of correcting some abuse in the profession generally this might be justifiable; but when it is an individual attack, I could not conceive it possible that any one would be so deficient in manliness as not to dare to avow his name.

I am, sir,

Your obedient servant,

J. TURNER.

Macclesfield, May 23d, 1842.

ADDITIONAL CASES  
IN PROOF OF THE  
EFFICACY OF IODINE AND  
MERCURY,  
IN THE CURE BOTH OF THE  
PRIMARY AND SECONDARY SYMP-  
TOMS OF SYPHILIS.

BY JOHN WICKENS WEST, M.R.C.S.L.

(*For the London Medical Gazette.*)

IN consequence of the success which attended the practice I have adopted for some time past, of administering iodine and mercury both in the primary and secondary symptoms of syphilis, I was induced to communicate to the profession, through the medium of the *MEDICAL GAZETTE*, the result of that experience, as exemplified in a few of the most recent and pointed cases. I have, in a subsequent number of the journal, the pleasure of noticing that the plan I pursued had been put in force by my friend, Mr. Dodd, Surgeon, of Northampton, whose efforts, in two cases of primary syphilis, were crowned with equal success; and I feel particularly obliged to him for his ingenuous conduct in immediately giving publicity to it. The combined influence of the two remedies appears to me, in all instances in which I have tried it, to obviate the necessity of ever pushing the mercury to an approach to salivation; and the effects are so mild, that the usual constitutional disturbance, which is produced in the system when under the influence of the latter remedy, is altogether prevented. Iodine, administered by itself in some form or other, especially in that of the hydriodate of potash, has succeeded in the hands of many practitioners, where mercury had signally failed, and was, moreover, producing prejudicial effects on the constitution.

Now the administration of the two medicines at the same time has succeeded in cases where both iodine and mercury, given separately, had proved altogether ineffectual. There is no disease incidental to the human frame which is more frequently treated by empirics and empirical remedies than syphilis in all its forms, from the chancre on the penis to nodes on the shins; and the principal ingredient of the medicines so administered is mercury in some shape or other. The sad effects on the constitution, of the inordinate use of this remedy, is constantly witnessed by medical men; and in order to prevent it, in some degree, we ought to endeavour to introduce into general practice a plan of administering an efficacious remedy, which is not so likely to expose, even in empirics' hands, the patient to the dangerous influence of a powerful medicine, which often produces a more baneful effect on the constitution than the disease it is intended to eradicate: "the friend often does more mischief than the foe." I shall now illustrate the particulars of several cases in addition to those already published in this journal, in support of the opinions adduced.

CASE 7.—George King, æt 22, by occupation a servant, applied to me November 4th, 1840, with a copper-coloured eruption, extending over the whole body, ulcerated throat and tonsils, and severe pains in his limbs, especially at night. He informed me, that about twelve months ago he contracted two large chancres on the glans penis, and slight discharge from the urethra. He took some medicine from a druggist until his gums became tender; and shortly after this the sores healed without local applications. Two months from that period he was again so unfortunate as to have another chancre on the glans penis, and likewise a suppurating bubo in the right groin, both of which, however, under medical treatment, he got rid of, and he continued for some months apparently without a vestige of the disorder; indeed until a short time before consulting me for the symptoms he now labours under.

I ordered him to take the following medicine:—

℞ Tinct. Iodinæ, ℥ xx. ex cyatho aquæ, ter quotidie.

℞ Pil. Hydrarg. gr. iss.; Pulv. Ipecac. Comp. gr. iv.; Conf. Rosæ, q. ut. fiat pil. nocte maneque sumend.

℞ Solut. Chlorid. Sodæ, ℥ iss.; Aquæ Puræ, ℥ ivss. fiat gargarisina frequenter utend.

Nov. 10th.—Complains less of his throat, and the ulceration on the tonsils healing: the eruption as before. Has better nights, being freer of pain.

14th.—The throat has got well; the eruption disappearing, and in every other respect much better.

Cont. Med.

21st.—Quite recovered.

CASE VIII.—W. T., æt. 32, applied to me Dec. 16th, 1840, with chancre and a bubo in each groin, both of which were fast approaching to a state of suppuration. He was suffering from languor and debility, in consequence of a long use of mercurial medicines, which had appeared rather to increase than diminish the disease.

I recommended the following:—

R Tinct. Iodinæ, ℥xv. ex cyatho aquæ ter die.

R Pil. Hyd. gr. iss.; Pulv. Ipecac. c. gr. iij.; Conf. Rosæ, q. s. ut. ft. pil. omni nocte sumend.

22d.—Has gained strength since I first saw him, and the character of the sore on the penis slightly improved. The buboes, under the use of linseed poultices, have been freely discharging, and they appear disposed to heal.

January 2d.—The chancre is nearly healed, as well as the buboes: still suffers from debility and loss of appetite. I recommended change of air, and to continue the iodine drops and pills.

12th.—Heard from him this morning, and he informed me the sores were healed, and that he felt better from the change.

24th.—Has returned from the country in better health, with the chancre and buboes quite healed.

REMARKS.—The buboes in this case were promoted towards suppuration evidently by the action of the mercury on the system. It acts as a universal stimulant, particularly on the lymphatic system; and this is one reason why buboes generally suppurate at the close of a mercurial course.

CASE IX.—J. R., æt. 44, an unmarried man, consulted me in consequence of labouring under an eruption on the skin of a leprous character, especially affecting the left leg and thigh; and also a chronic enlargement of the inguinal glands of the left groin, which followed an attack of gonorrhœa and chancre, and had continued ever since, although he had been cured of the latter disease for some time. He informed me he had led a very irregular life, and had several times contracted the venereal disease, for which he had been treated with mercury. He had at times a pain and difficulty in voiding his urine, which, on examination, I found to depend upon the enlargement of the prostate gland. I ordered him—

Balneum Calidum alt. Noct.; R Ty. Iodinæ ℥xx. ex aqua ter die. Pil. Hydrarg. gr. iij.; Pulv. Ipecac. Co. gr. iv.;

Conf. Rosæ, q. s. ut ft. pil. nocte manequè sumend.

R Potassæ Hydriodatis, 3j.; Ung. Cetacei, 3j. ft. unguentum, hujus pauxillo oblinatur perineum nocte manequè.

January 10th.—It is now ten days since I first saw him, and he complains of less pain and difficulty in making water, and there is an evident improvement in the eruption.

22d.—Symptoms much improved; pain in making water entirely removed.

Cont. Guttæ et Pilul.

22d.—The eruption disappeared, and in every respect quite recovered, with the exception of slight enlargement of the inguinal glands.

REMARKS.—In this case there was combined with the secondary symptoms evident chronic enlargement of the prostate gland, on which the use of the hydriodate of potash locally applied had a very marked effect.

CASE X.—Mary Hewlitt, æt. 26, a woman of dissipated and profligate habits, and who had been on the town for some years, applied to me with the following symptoms:—Ulcerated throat, swelling on the os frontis, excruciating pains at night, and a foetid discharge from the nostrils. She stated she had had the venereal disease several times, and had taken a great quantity of pills at various times, which, on one occasion, caused her to have a sore mouth. I ordered her the following:—

R Tinct. Iodinæ, ℥xx. ex aqua ter quotidie.

R Pil. Hydrarg. gr. iij.; Pulv. Opii, gr. j. omni nocte sub forma pilulæ.

This plan was persevered in for six weeks, when I had the satisfaction of noticing considerable improvement in her symptoms. The swelling on the os frontis had disappeared, and she experienced less pain at night.

I had not an opportunity of seeing the termination of the case, as the woman quitted the town.

CASE XI.—Charles Boyt, æt. 30, contracted a large Hunterian chancre on the glans penis. He immediately applied to a druggist, who prescribed mercurial pills, which he persevered in for some time, but without any improvement in the appearance of the sore; and he was experiencing considerable constitutional irritation. When I saw it, it was very unhealthy, with indurated base, and much irritation of the surrounding parts. I ordered Lotio Nigra parti affectæ.

Pil. Hydr. gr. iij.; Pulv. Opii, gr. ½; fiat pil. bis quotidie sumend.

R Iodinæ ℥xv. ex poculo aquæ ter quotidie.

October 8th.—Chancre much the same,

but with less irritation of the surrounding parts. Has a slight copper-coloured eruption on the breast and arms.

Cont. Pilul. et Guttæ.

14th.—The eruption has disappeared, and the chancre appears disposed to heal.

Cont. Guttæ. Omit Alia.

21st.—Chancre nearly healed.

30th.—Chancre well.

CASE XII.—Mary James, æt. 22, a woman of the town, was received into the Poole Union, October 4, 1840, with a bubo in the left groin, inflamed and painful; chancrous excoriation in the vagina, and spongy, fungous excrescences near the anus, which latter symptom she had had some time. Has had the venereal disease several times, and has taken much medicine. I ordered—

R Argenti Nitratis, gr. vj.; Aquæ Pluvial, ʒij.; ft. lotio et applicetur paululum parti affectæ nocte manequæ.

R Pil. Hydr. gr. iv.; Pulv. Ipecac. c. gr. v. ft. pil. omni nocte sumend.

Tinct. Iodinæ, ℥xx. ter quotidie ex aqua.

8th.—The excrescences about the anus have nearly separated from the part; and the chancre looks healthy, and discharging.

Cont. Pilulæ et Guttæ.

14th.—The chancre healed, and the other symptoms improving rapidly.

21st.—Quite well.

CASE XIII.—Wm. Tailor, æt. 46, by trade a shoemaker, applied to me in consequence of severe pains in his limbs, which he supposed to be rheumatic. On the tibia of the right leg there was a painful swelling, which had the appearance of a chancre. He told me about ten years ago he contracted a chancre on the glans penis, but soon got rid of it under the use of medicine, and from that period, until about a month ago, has never experienced any thing of the kind.

Balneum Calidum alternis noctibus.

Fotus Papaveris parti affectæ omni nocte manequæ.

R Pil. Hydr. gr. iij.; Pulv. Ipecac. co. gr. v. Ft. pil. bis quotidie sumenda: sum. Tinct. Iodinæ, ℥xx. ex aqua.

This treatment was continued a fortnight without intermission, when he lost the pains in his limbs, and the swelling subsided.

REMARKS.—There can be little doubt, from the history of this case, that it was one of secondary symptoms; and in this instance as in others in which I have tried it, the iodine and mercury, given in conjunction, had a very rapid and beneficial effect. From the experience I have already had in these remedies, I think there is very little doubt

but what they will be found materially to relieve, and, in the majority of instances, cure, almost any form or stage of the venereal disease.

CASE XIV.—Mary Dymick, æt. 45, married, and the mother of six children, applied to me August the 5th, 1841, with an extensively ulcerated throat: both tonsils were entirely gone; an eruption of the leprous character on the legs and arms; violent pains in her limbs, and a large node on the tibia of the right leg. Her husband communicated a chancre to her about two years before, and she neglected to adopt any plan for some time. However, after taking pills for a few days only, she got well. At the end of ten or eleven months from the period she first observed the sore, she discovered an eruption on the arms, which was then copper-coloured, and did not assume its present nature for some months. This eruption was soon followed by sore throat and pains in her limbs, which increased rapidly.

Solut. Chlorid. Sodæ, ʒiss.; Aquæ, ʒivss. ft. gargarisma frequenter utend.

Cap. Pil. et Tinct. Iodinæ.

15th.—The eruption is rather better, but still violent pains in her limbs.

September 6th.—Her throat is better; eruption gone, and the node less painful.

I did not attend her to the termination of the complaint, but understood she gradually improved in health.

REMARKS.—This was a severe case of secondary symptoms, in which very little medicine had been taken for the primary disease. The result of the practice adopted was a mitigation of the symptoms, although not entirely eradicated at the time she omitted the remedies.

## TUMORS FORMED ON THE TISSUE OF CICATRICES.

M. GIMELLE brought before the Royal Academy of Medicine at Paris a young soldier having upon his body numerous cicatrices, many of which had become the seat of tumors of a doubtful nature. For instance, beneath the left ear was a tumor of pale colour, soft, unaccompanied by pain, and united to the skin by its whole circumference. On one of the shoulders was to be seen an analogous production, except that the sides of this were more raised, and it was supported on a pedicle; its centre was not completely cicatrized, and gave vent to a purulent exudation. The same person bore on the wrist another deep wound, which appeared to have involved the radial artery, and the corresponding fingers were flabby, swelled, and livid. These different growths, the nature

of which is not accurately decided, gave rise to much interesting discussion. MM. Velpeau and Gerdy regarded the production beneath the ear as very analogous to, if not identical with, the keloide. That on the shoulder, which the first of these surgeons thought also a pediculated keloide, was considered by M. Gerdy as a vegetation, similar to those which frequently form on wounds, which not being checked had grown prominent, and assumed the form of a mushroom. M. Velpeau feared the return of the tumors if removed. MM. Gerdy, Londe, Blandin, and Laqueau, thought they might be extirpated with very good hope of cure."—*Archives Générales de Médecine.*

ON THE USE OF SOLUTION OF CHLORINE IN SCARLET FEVER.

By DR. CLEMENS,  
Of Frankfort-on-the-Maine.

THE author found the Aqua Oxymuriatica (solution of chlorine) of the Prussian Pharmacopœia decidedly antiphlogistic, and beneficial in every epidemic of scarlatina. After the inflammation of the throat, and the congestion towards the head, had been diminished by an emetic, and the frequency of the pulse lessened, or bad symptoms about the brain and eyes removed by leeches, the author gave gentle cathartics for several days running. He then prescribed a mixture consisting of from one to four drachms of aqua oxymuriatica, and three or four ounces of distilled water; the whole to be taken in twenty-four hours by a child from eight to twelve years old. He added no syrup, in order to avoid decomposition. Dr. Clemens continued its use during the period of desquamation, but omitted it sometimes for days together; alternating it with purgatives if the bowels were costive.—*Schmidt's Jahrbücher.*

LECTURES  
ON THE  
PRINCIPLES AND PRACTICE OF  
PHYSIC,

Delivered at King's College, London,

BY DR. WATSON.

*Suppression of urine. Diabetes: qualities of the urine; symptoms; anatomical appearances; general pathology of the disease; treatment. Diuresis.*

SYSTEMATIC writers have adopted the term *Ischuria* to express that condition in which no urine is voided. It includes, therefore, those cases in which no urine is secreted; and those in which, although secreted, it is not discharged from the body. Now these two conditions are exceedingly different from each other in most respects; and I shall prefer making use of the two plain English names, *suppression* of urine, and *retention* of urine. Even these terms are sometimes confounded with each other. In *suppression*, the secretion is suspended: in *retention* it may be as active as ever. Retention of urine is a surgical case; involving points of great practical interest. Suppression belongs to the physician: and the technical term for it is *ischuria renalis*. It is sometimes spoken of as paralysis of the kidney; a phrase to which I object, because I think palsy is a word which ought to be restricted to a loss of power over the muscular fibre.

This affection usually occurs in persons who are advanced in life, and inclined to corpulency. Why it should be so I cannot tell you, but such is the fact, as stated by most observers. Sir Henry Hallford has related one of five instances of this disease that he had met with in the course of seven-and-twenty years. He says it was an exact copy of all the others that had fallen under his notice: and as his account of the general

course of the symptoms coincides with the statements of other writers, I may give you his narrative, in lieu of a formal description.

"A very corpulent robust farmer, of about 55 years of age, was seized with a rigor, which induced him to send for his apothecary. He had not made water, it appeared, for 24 hours. But there was no pain, no sense of weight in the loins, no distension in any part of the abdomen:—and therefore no alarm was taken till the following morning, when it was thought proper to ascertain whether there was any water in the bladder, by the introduction of the catheter: and none was found. I was then called (says Sir Henry), and another enquiry was made, some few hours afterwards, by one of the most experienced surgeons in London, whether the bladder contained any urine or not: when it appeared clearly that there was none. The patient sat up in bed, and conversed as usual, complaining of some nausea; but of nothing material in his own view: and I remember that his friends expressed their surprise that so much importance should be attached to so little apparent illness. The patient's pulse was somewhat slower than usual; and sometimes he was heavy and oppressed."

"I ventured to state (continues the author) that if we should not succeed in making the kidneys act, the patient would soon become comatose, and would probably die the following night: for this was the course of the malady in every other instance that I had seen. It happened so: he died in 30 hours after this, in a state of stupefaction."

This is the curious and important point in the history of such cases. If no urine be separated from the blood, coma soon supervenes, and death. It is believed that these consequences result from the detention of *urea* in the system. Urea is a mere excrement, which, in health, is removed from the blood by the kidneys, as fast as it enters that fluid. When it is not so carried off,

it accumulates in the blood, circulates with it to every part of the body, and acts as a poison, especially upon the brain. This is one of several cases, shewing that the carrying fluid of the body may become the vehicle of disease and death if it be not duly purged of deleterious matters which are incidental to the unceasing processes of organic life. If *carbonic acid* be not extricated by the lungs, the animal functions are as certainly and almost as speedily extinguished by that gas, as the flame of a taper might be. And we have recently seen that when the outlet from the liver is shut up, when the blood is not purified from the excrementitious *bile*, the powers of animal life are weakened, and sometimes utterly and rapidly destroyed.

Suppression of urine, for a considerable time, is not, however, necessarily or universally fatal. Patients labouring under the epidemic cholera would secrete not a drop of water for some days; and yet recover. It was remarkable how entirely free such patients were from any approach towards coma. Was the urea here drained off from the blood in the enormous and unnatural flux from the stomach and bowels? I think it probably was: but I do not know that any chemical search was ever made for that substance in the fluids so effused. There are, however, some very singular instances on record of persons who have passed days and even weeks without secreting urine; and without shewing any other indication of impaired health. What degree of credit such narratives deserve I do not know; but assuming that there was neither fraud nor mistake, it may be suspected that either the natural secretion was compensated for by some vicarious or supplemental discharge; or that a *small* quantity of urine was actually separated by the kidneys. "If any water, however small the quantity (remarks Sir Henry Hallford) had been made in these cases, I should have thought it possible that the patients might have recovered: for it has often surprised me to observe how small has been the measure of that excrementitious fluid which the frame has sometimes thrown off, and yet preserved itself harmless. But the cessation of the excretion *altogether* is universally a fatal symptom in my experience, being followed by oppression on the brain." The same eminent physician states that in three of his five cases there was observed a remarkably strong urinous smell, in the perspiration, for 24 hours before death. This I believe is of common occurrence in such cases. Other patients have vomited, or passed by the bowels, watery matters possessing some of the sensible qualities of urine: and a urinous fluid is said to have been found in the ventricles of the brain in some of the fatal examples.

I have spoken of suppression of urine as a malady, though it probably is never any thing more than a symptom. Yet it is one of those symptoms which from our uncertainty respecting their origin and determining cause, we are obliged to treat, and to study, as if they were substantial diseases. In the only well-marked instance that I have seen of suppression of urine coming on in an apparently healthy person, some blood had appeared in the urine for a day or two before the secretion was totally suspended; and the kidneys were found gorged with blood. Extreme congestion, or inflammation, of the substance of the gland, is probably at the bottom of many of these cases. The same train of symptoms supervene not unfrequently upon organic renal disease. They happen, too, when the ureters become impervious, from disease, or from impacted gravel. In this condition urine continues to be secreted, for a time at least, and distends the ureter behind the seat of the obstruction. The apoplectic state which ensues may arise from a re-absorption of the secreted fluid; or, in consequence of the obstacle, the secretion itself, after going on to a certain point, may stop, and then the case becomes a case of suppression.

Respecting the treatment of this most formidable condition I can say but little. Cupping upon the loins, venesection if warranted by the state of the pulse, the hot bath, sudorific medicines, purgatives, and large warm enemata, seem to me the kind of remedies indicated. To endeavour to force the secretion of urine by strong stimulating diuretics, would strike one, *à priori*, as being hazardous. Yet this practice has its advocates; and should experience declare in its favour, theoretic objections ought to be disregarded. If benefit is so to be obtained, certainly the best drug for our purpose will be cantharides. Dr. Elliotson refers to some examples of its success in the hands of Sir Astley Cooper; and afterwards of another practitioner who took the hint from Sir Astley. He suggests that as the tincture of cantharides is a very uncertain preparation, the remedy should be given in the solid form, a grain at a time, and that a large blister should be laid upon the loins. Beyond these hints I am unable to give you any assistance towards the management of this obscure but serious complaint.

The opposite condition of the kidney, in respect to its peculiar function—that, I mean, in which its secretion is largely and morbidly *augmented*—is scarcely less fatal than the total suppression we have just been considering; but it is not so rapidly fatal. When the amount of urine secreted and passed is permanently too great, when

it is constantly running off, as it were, from the system, the patient is commonly said to have *diabetes*: from *διαβαίνω*, to run through.

But it is not every case of an excessive flow of urine that deserves to be called diabetes. Great quantities of aqueous urine are made by hysterical and nervous patients. We all make more water in cold weather than in warm; the functions of the skin and of the kidney compensating each for the occasional defect of the other. Certain drugs and articles of diet are also well known to cause a temporary excess in the quantity of urine secreted.

In fact, although the quantity of the urine voided is the most obvious and striking symptom of diabetes, its definite and characteristic symptom is a most remarkable change in the *quality* of that liquid: in its becoming loaded with sugar. You will find, indeed, two species of diabetes mentioned by many authors—the diabetes *insipidus*, and the diabetes *mellitus*. The former term ought in my opinion to be abolished. If it refers merely to an unnatural abundance of urine, not otherwise differing in its composition from healthy urine than in containing a large proportion of water—by calling such a state diabetes, we link together in the same genus two essentially different conditions. In true diabetes the urine is never without sugar. The quantity may indeed be small; and it may not be sensible to that coarse test, the *taste*: but modern observers almost all agree in rejecting any species of diabetes, in which the urine is not at all saccharine.

The sensible qualities of diabetic urine differ strikingly, in many particulars, from those of the urine of health. Its chemical quality differs strikingly too, as I have already told you; but it is in one particular only. Fortunately no particular skill is required to recognize the morbid secretion.

Diabetic urine is light coloured, and transparent; of a pale straw, or greenish tint. Its odour is peculiar. According to Dr. Prout the scent somewhat resembles that of sweet hay, or that of milk; but to my nose it is more like the faint smell of certain apples, or rather of an apple chamber. Its taste is, more or less decidedly, sweet. Notwithstanding its limpid and aqueous appearance, diabetic urine is remarkably heavy.

It was long believed that the quantity of urea in diabetic urine was reduced much below the natural standard; and that the sugar was somehow formed at the expense of the urea. Dr. Prout, in his earlier researches, always detected a little, and but a little, of this peculiar principle. Later observations have shown, however, that the urea is not so scanty; nay that it is generally as abundant as in the urine of health, and sometimes even more so. The presence of

the sugar conceals the urea; interferes with the action of the ordinary tests of that substance. By certain modes of procedure, which I need not stop to describe, the urea may readily be discovered: and it is often found, I say, to be rather excessive than deficient. The usual saline matters belonging to healthy urine are present also in that of diabetic persons; and in the same *relative* proportions; but, as might be expected, their *absolute* amount, in a given quantity of the liquid, is very much diminished. In short, the only essential deviation from the standard chemical constitution of the urine is, that it holds in solution a quantity of sugar. This explains its peculiar odour, its sweetness, and perhaps its excessive quantity. It explains also another very characteristic property of diabetic urine; I mean its high specific gravity. In general, you know, the specific gravity of the urine is inversely proportional to the quantity secreted in a given time; the more copious and dilute it is, the lighter it is. But in diabetes, so strong is the saccharine impregnation that the specific gravity more than keeps pace with the increased quantity of the liquid secreted. The specific gravity of diabetic urine is always much higher than that of healthy urine.

The *quantity* of urine secreted and voided is sometimes enormous: far more than could be supplied by the quantity of fluid taken as drink, although that, as I shall presently explain, is excessive too. A healthy person passes from one to three or four pints of urine in the 24 hours. The quantity, as you well know, is liable to considerable variation: perhaps the average may safely be laid at about forty ounces. But patients in diabetes will void 40 *pints* in the same time. I have myself seen 26; 13 or 14 are not uncommon; and cases are recorded by writers of credit and veracity, in which 70 pints were passed daily. Nay, one Italian author declares that 200 pints have been discharged in that time.

The saccharine matter thus held in solution may be obtained in its solid form by evaporating the urine. I have seen large flat cakes of beautifully crystallized diabetic sugar. It differs somewhat from common sugar, the produce of the sugar cane; and approaches more nearly to the sugar of grapes. By rapid evaporation of the water a thick syrup is procured resembling treacle; but Dr. Mac Intyre, who has presented to our hospital-museum some very perfect specimens of this sugar, informs me that to get it well crystallized, the evaporation in a steam bath should be stopped while the urine is still of thin consistence. It may be quickly reduced to one half, perhaps, of its original quantity. Then it should be set aside, in shallow plates; and in the course

of ten days or a fortnight the sugar will be deposited in a regularly crystalline form.

The sugar is sometimes so abundant, that it undergoes a rude crystallization as the urine dries, wherever it happens to fall. A girl who was in St. Bartholomew's Hospital, while I was a student there, observed that if her water was accidentally sprinkled upon her black stuff shoes, every drop left a white powdery spot behind it. So also an aged patient under Dr. Mac Intyre's care expressed to him her alarm at finding that her black worsted stockings were covered with a white dust, from the same cause. I remember hearing from a diabetic patient in the Edinburgh Infirmary, that his attention was first drawn to his urine by the number of flies and wasps which its sweetness attracted to the chamber-pot.

This daily produce of sugar from the laboratory of the human body, is surely a very singular and surprising phenomenon. Sugar is not a constituent of healthy urine. Dr. Prout (who is more consulted on this subject than any one else, and whose experience in respect to it is commensurably great) says that he has never known saccharine matter to occur in the urine of any other animal than man. I once had a coach-horse which I supposed might have diabetes. He was a greedy feeder, and drank eagerly, yet he grew thinner and thinner; and wherever I had occasion to stop, there he invariably began to stale: so that I became thoroughly ashamed of his leaking. Dr. Prout was good enough to examine his urine for me. It contained no sugar, but its healthy properties were much changed: it had less than the natural quantity of hippuric acid, and more of earthy matters. The disease, he tells me, is known at the Veterinary College; whence specimens of such urine have been sent to him for inspection: but it is not true diabetes.

The unnaturally high specific gravity of diabetic urine is a constant quality; and you must attend to this, for it is almost always a faithful index, not only of the presence, but of the severity of the disorder. Dr. Prout places the specific gravity of healthy urine between 1015 and 1025, that of distilled water being represented by 1000. Different authors vary somewhat in their estimate of the natural standard; but we may be content to follow Dr. Prout. He says that the specific gravity of diabetic urine has been stated to vary from 1020 to 1050: that he has many times seen it higher than this, but very seldom so low. In fact it ranges generally between 1030 and 1060; and the average may be taken at 1040.

So much with reference to the quantity and qualities of the urine discharged in this complaint. It is attended, however, as you

may suppose, with other and important symptoms.

As so much fluid is evacuated from the body through this channel, it might be expected that the *other* channels for the excretion of liquid matters would be comparatively dry: and so they are. The skin is arid, harsh, and unperspirable. The patients tell you that they never sweat: that they cannot get into a perspiration. This is a very general symptom: yet in some few patients, especially as the fatal period of the complaint draws near, the surface readily becomes humid. Again, the bowels are mostly costive, and the *fæces* remarkably solid and free from moisture. The tongue is dry, parched, and sticky; sometimes unnaturally red and clean: and the waste of watery particles from the system seems to be felt and expressed by the inordinate thirst which the patients suffer. Their thirst is often insatiable. I remember one girl telling me that when she was debarred from an excess of water to drink, she would get up if she heard it raining in the night, and catch some of the descending drops to satisfy the tormenting sensation of thirst. And another patient, a very sensible fellow, informed me that, believing it could not be good for him to drink so much, and feeling no confidence in his own resolution to refrain, he was in the habit of betaking himself in the summer time to the fields and dry pastures, where no water was at hand to quench his strong desire for it. The appetite for food is often, but not always, equally keen: and the patients, especially those in the lower ranks of society, are apt to think, while they wonder at their weakness, that there cannot be much the matter with them, since they continue to eat and drink so famously.

Again, the enormous daily drain upon the system may be expected to cause various symptoms and sensations which may all be referred to debility and defective nutrition. Dr. Henry published a table, shewing the quantity of solid extract in every wine pint of urine of different specific gravities from 1020 to 1050. Taking 1040 as the average specific gravity, and ten pints as the average quantity of the urine discharged daily, the patient would in this manner lose, every 24 hours, 15 ounces 7 drachms—or more than a pound and a quarter—of solid materials.

We need not be surprised, therefore, at the hunger, the wasting, the hectic fever, the feeling of emptiness and sinking at the stomach, the debility, the chilly state of the body, and especially of the extremities, the aching and sense of weariness in the loins and legs, the aversion to exercise, the loss of virility; all of which symptoms are generally present. I may add, to complete the picture, some others, enumerated by Dr. Watt, and

confirmed by Dr. Prout, and consistent with my own experience of the disease. They are, uneasiness in the stomach after meals, flatulence and acid eructations, dimness of vision, redness of the whole interior of the mouth, sponginess of the gums, looseness of the teeth, and some degree of irritation and inflammatory redness about the external orifice of the urethra: these last are symptoms noticed in persons dying of inanition. Again, listlessness and depression of spirits, weakness and peevishness of temper: "the once vigorous mind becomes feeble, oblivious, and vacillating—the once amiable temper, fretful, suspicious, and intolerant." With all this there is a peculiar faint and unpleasant odour of the breath and person; an odour which Dr. Prout says is hay-like, which some call melleous, but which reminds me, as I said before respecting the urine, of the smell of a room in which apples have been kept. I have recognized the complaint, upon first entering the sick chamber, by this peculiar scent.

Diabetes is generally a chronic disorder, creeping on at first insidiously, and spreading itself, under judicious management, over many years. Yet it is sometimes fairly entitled to be called an acute disease; for it occasionally breaks out suddenly, is attended with much febrile disturbance, and runs a short course, uncontrolled by any treatment. One such instance I have seen. Much more frequently it proves fatal through the supervention of some organic mischief, such as debility is calculated to foster and develop. It often becomes associated in its progress with pulmonary disease, especially with tubercular phthisis. So common is this, that some persons have thought it universal. But it is not so. I have myself witnessed more than one or two dissections of persons dead of diabetes, whose lungs did not contain a single tubercle. Sometimes the disease terminates in incurable dropsy: and sometimes the patient is cut off suddenly, either by apoplexy, or by some peculiar affection of the stomach.

There is some kind of connexion between diabetes and certain affections of the skin, and of the subjacent reticular membrane. Dr. Prout remarks that it usually *follows* cutaneous complaints, but *accompanies or precedes* those which involve the cellular tissue. Persons have been known to lose chronic eruptions upon the supervention of diabetes. On the other hand, carbuncles and malignant boils are frequently the companions of that disorder.

The examination of the dead body throws little or no light upon the pathology of diabetes. We naturally look with interest to the kidneys. But we find nothing there to explain the symptoms noticed during life. What I have usually remarked has been a deep purplish red colour of the kidneys,

which were veined and vascular, but not otherwise altered in texture. Andral and others tell us that the kidneys are found hypertrophied in diabetes. But hypertrophy, and unnatural vascularity, are circumstances which we are not surprised at when we reflect upon the vastly increased quantity of work which the glands have been performing. We must regard both these unnatural conditions rather as being the consequence, than as being the cause, of the morbid flow of urine. In one instance, after sudden symptoms of gastritis, which followed the incautious potation of strong ale, I found the mucous membrane of the stomach distinctly inflamed, in its cardiac portion. I have found also the mesenteric glands diseased, converted almost entirely into bone. But neither of these changes are constant. They were purely accidental in those particular cases.

What, then, is the origin and source of this strange complaint? whereabouts in the body is the sugar formed? is it made, by the kidneys, from the blood? or is it made, from the food, by the stomach; and carried into the blood to be simply cast out through the urinary channels? or is it elaborated in some intermediate stage of what Dr. Prout has called the secondary assimilation; which includes the formative and the destructive processes that take place in the body subsequently to the act of sanguification? These questions, which are full of interest, have been much debated: and until very lately pathology was unequal to their solution. It was naturally thought that, if the sugar pre-existed in the blood, and was only withdrawn from it by the kidneys, it would be discoverable in the blood. Yet able chemists sought for it there in vain. Hence it was inferred, that by some new combination of its elements, saccharine matter was actually formed in the kidneys. The chemistry and the reasoning were both faulty. Sugar has, now, been detected in diabetic blood. It is detected with some difficulty, partly perhaps because its presence is masked by the albumen of the serum, but partly because its quantity is small; and its quantity is small because it is continually decanted out of the blood, as fast as it enters, and with it a profusion of water also, through the kidneys. In this respect the sugar and the urea are alike. They are both excretions which the blood is in haste to cast forth. It would seem also as if the sugar necessarily carried with it a large quantity of aqueous fluid from the blood, and was simply diuretic. When the amount of sugar eliminated is diminished, as by certain remedies it may be, the quantity of urine diminishes too.

Traces of sugar had, I believe, been found in the blood by some previous enquirers: but it is to Mr. M'Gregor, of Glasgow, that

we are indebted for the full exposition of this interesting fact. His researches, published last year (1837) in the *MEDICAL GAZETTE*, have thrown a new and strong light upon the pathology of diabetes.

By a peculiar process, he did, I say, that which many preceding chemists had failed to accomplish; he detected sugar in the serum of the blood of diabetic patients. The serum had a milky appearance he says; and I have seen that myself: its specific gravity was above the healthy standard. Having coagulated the serum by heat, he carefully dried it; then cut the dried mass into very small pieces, and boiled them in distilled water; and lastly, he evaporated the decoction to a certain point. To the liquid thus concentrated he added a portion of yeast, and the presence of sugar was manifested by the fermentation which ensued, and which lasted for several hours. Yeast, I should tell you, is a most delicate test of sugar, and will readily detect half a grain in two ounces of liquid.

Mr. M'Gregor went a step farther back. He obtained, by means of an emetic, the digested food from the stomachs of two men who had dined two or three hours before. One man was in health; the other had diabetes. In each case the food had been of the ordinary kind. Applying, after due preparation, the test of yeast, he found that the vomited matters fermented strongly; especially those from the diabetic patient.

Then he varied the experiment. Thinking that the sugar, in these cases, might have been introduced in the vegetable portion of the food, he adopted precautions to exclude that possible source of fallacy. He administered to a healthy man, and to a diabetic man, a vomit, and a purge; to clear out the alimentary canal. Then he fed them upon roast beef and water, and nothing else, for three days. Then, three or four hours after a meal, the contents of their stomachs were procured by the operation of the sulphate of zinc, as an emetic; and treated as in the former case. What the healthy man vomited did not ferment at all. What came from the diabetic patient fermented "pretty briskly."

The fault, then, we may safely conclude, lies in the *digestive* organs. Instead of healthy and nutritive chyle, saccharine matter is prepared by the stomach, and enters the circulation. That which should be converted into muscle, and fat, and bone, and nerve, and membrane, is hurried out of the system, as sugar, with the urine. Thus far we see our way with tolerable clearness. But *why* the stomach should cease to perform its accustomed chemistry upon the food, and even upon sugar itself as an article of food, we have not yet learned. That single important step is still wanting to the complete solution of the pathological problem.

I may mention that Mr. M'Gregor carried his enquiries farther still, and met with some curious results. He examined the saliva; the *feces*; and the sweat. He found sugar in the saliva. He could find none in the sweat. The *feces* of one patient, allowed to dry spontaneously, became covered, after the lapse of some time, by distinct crystals of sugar. And yeast having been administered to two patients, in ounce doses, after each meal, had soon to be discontinued, because the patients, to use their own expressions, felt as if they "were on the eve of being blown up."

We know but little about the *causes* of diabetes. It is not a very common disorder; and in those who become afflicted with it, there probably has existed a predisposition to it. Dr. Prout remarks that the complaint runs sometimes in families, and is inherited. I have had under my own observation, for some time past, two children, brother and sister, each affected with diabetes. The same author mentions among the predisposing causes, long-continued intemperance, and especially the immoderate use of spirits, severe evacuations, excessive labour joined with a poor accented diet. Distress and anxiety of mind are held also, and justly I think, to be among the predisposing causes. It occasionally seems to be produced, at once, by the operation of some exciting cause, such as exposure of the body to cold; or the drinking of large draughts of cold fluid while the person was hot and perspiring. Dr. Bardsley states that, in twelve instances of the disease which had fallen under his own notice, the patients attributed their ailment to one or the other of these two causes. Now these are common causes of disease: and that a predisposition does exist is probable from the fact, that where the exciting cause has acted on several individuals at the same time, one alone has become affected with diabetes. There is a narrative illustrating this, by Dr. Marsh, in the third volume of the *Dublin Hospital Reports*. A patient of his traced the apparent origin of his diabetes to exposure to wet, cold, and privation, at sea, while in imminent danger of shipwreck. Another of the crew fell ill of ague. Others escaped entirely, or had only common colds.

If the account which I have been obliged to give you concerning the intimate nature, and the causes, of this curious malady should appear unsatisfactory, so also, I fear, will what I have still to say respecting its cure. I dare not affirm that diabetes, although it seems a merely functional disorder, has ever been cured. Dr. Prout has known some few patients, two perhaps, or one, recover. Apparent recoveries—nay, apparent cures—are not very uncommon. And this it is of great importance to know. Remedies are

not useless because they fall short of their full scope. It is better to keep a man on the edge of a precipice, if you cannot pluck him away from it, than to let him fall over. And many diabetic patients are kept in this predicament of dangerous safety. There are certain remedies that exercise a strong controlling influence over some of the most prominent and troublesome of the symptoms; and that sometimes even restore the patient to a state which he mistakes for health; and which a medical man, unwarned of its fallacious character, might also mistake. The urine may recede within the limits of health. There may remain one morbid circumstance only, and that of a nature easily overlooked: indeed it is sure to escape observation if it be not especially looked for. I allude to the unnaturally high *specific gravity* of the urine. So long as the density of the urine continues permanently and decidedly above the healthy standard, there is no real security. The smallest disturbing cause—exposure to cold, an intemperate meal, unusual exertion and fatigue, sudden or strong mental emotion—may bring back all the symptoms in their former severity. If these and similar hurtful agencies can be averted, life may sometimes be prolonged, in much comfort, for many years.

There are three objects to be kept in view, in the treatment of every case of diabetes.

First, to restore the defective power of the digestive apparatus:

Secondly, to cut off, or restrict as much as possible, the supply of saccharine matter from without:

Thirdly, to mitigate or remove the most distressing symptoms.

If we could achieve the first of these objects, the other two would fall out of sight; for the disease, which is really a variety of dyspepsia, would be cured. But hitherto all the resources of our art have, in this respect, been baffled. Our main hope of ultimate success must lie in the regulation of the *ingesta*; whereby, also, the second indication is to be fulfilled. Some of the food is, in every case, carried to the proper account, or the patient would speedily die. If we can succeed in directing a sufficient amount of healthy nutriment to the organic tissues of the body, the draining away of any superfluous sugar will be borne well enough.

About the beginning of the present century, Dr. Rollo discovered and taught that a diet composed exclusively of animal matters had a signal effect in reducing the quantity and in diminishing the sweetness of diabetic urine. Mr. M'Gregor's experiments tell us why this is. Animal food furnishes but scantily the materials for the formation of sugar. "The saccharine alimentary principles are chiefly derived (says Dr. Prout)

from the vegetable kingdom, and indeed constitute what may be called, by way of distinction, *vegetable aliments*." If, then, we can exclude aliments of this kind, and confine the patient to animal food alone, we thus cut off the supply of the *materies morbi*; and without indeed curing the disorder, suspend its worst effects. But unluckily very few persons can long endure this mode of living. So far as they can endure it, they are comparatively safe. We are obliged to relax, in some degree, the rigour of our rule: and it is curious to observe how suddenly and decidedly the saccharine properties and the quantity of the urine are augmented, when, by stealth, or by permission, the patient adds to his meal the smallest portion of vegetable food—even a biscuit or two.

We must therefore contrive to vary the animal diet as well as we can; encouraging the patient by a free license to choose among the different kinds of meat, game, poultry, and eggs, in their diversified modes of preparation, and admitting into his bill of fare as small an admixture as possible of vegetable substances. Green garden-stuff, the oleracea, spinach, cabbage, celery, and the like, may be taken with less risk of increasing the saccharine matters in the system, than potatoes, and those other articles of vegetable diet which contain a notable proportion of sugar, gum, or starch. All kinds of fruit must be forbidden. You will seldom be able to debar your patients entirely from bread: none should be allowed but such as is well fermented, and somewhat stale; and even that as sparingly as may be.

It is also of much importance to admonish the patient, whose appetite is generally ravenous, against eating too large a quantity, even of animal food, at any one time. Not only is the digestion still further weakened and oppressed by an intemperate meal, but the patient's life may be put in peril by every such act of unwise indulgence. Of this I have witnessed one example, and have heard of several more.

The quantity of drink should likewise be limited. It may properly enough consist of animal broths: and these should be taken *tepid*, for they are then more likely to be taken in moderation. The patients must, however, and will, have something else, to slake their urgent thirst. I have found (acting upon a suggestion of the elder Dr. Latham) that distilled water, acidulated with phosphoric acid, appeases, more than most things, that painful sensation. The water of the Bristol Hot Wells, which contains carbonate of lime in solution, is praised by Dr. Prout for the same purpose.

Dr. Christison gives an important caution in respect to drinks; viz. that, when the thirst has already been much indulged, the quantity of liquid taken must not be greatly

reduced all at once. Sudden failure of the vital powers has not unfrequently ensued upon abrupt changes of that kind.

Very numerous are the remedies which have been tried, and which have been recommended, for this disorder. I shall notice those only of which I have had personal, and in some degree favourable, experience.

The first of these is *blood-letting*, which has been strongly advocated by Dr. Watt, of Glasgow, and by Dr. Satterley, formerly one of the physicians to the Middlesex Hospital. It is not a remedy which would naturally occur to one's mind as being likely to prove of service in such cases; but both the authors I have mentioned speak of it in terms of high commendation. They affirm that, under small and frequent bleedings, the strength increases; the clamminess of the mouth, and dryness of the skin, diminish; and the blood, by degrees, assumes the buffy coat. I have once seen the method of frequent blood-letting fairly put to the test. At first the patient did seem to be benefitted by it; but she ultimately died: and I am satisfied that her death was accelerated by one bleeding too many, or by too large an abstraction of blood at one time.

This measure has the best chance of being useful, when the malady is recent, and attended with febrile disturbance. In chronic cases, in old persons, and whenever the debility is already great, venesection can seldom be requisite or proper; although even then, as Dr. Prout remarks, it may be borne better than one might expect. Local bleeding is, however, of much service in relieving local uneasiness. Leeches may be applied to the epigastrium, if the patient has tenderness there, or complains of a sense of fulness or of burning in the stomach. Cupping to the loins, if they greatly ache.

*Opium* is a treasure to us in this disorder. It quiets the nervous irritability of the patient, allays many of his most distressing sensations, and restrains in a remarkable manner the morbid profluvium from the kidneys. But you must not suppose, from observing these favourable changes, that you are curing the disease by it. It appears to control the diuretic influence of the sugar in the blood; but it does not banish the sugar itself. And, as far as my experience goes, Dr. Prout is in the right when he states that moderate doses of opium generally suffice to check the excessive discharge. Five grains of Dover's powder, for example, three times a day, will do as much good, and on the other hand be productive of far less inconvenience, than larger quantities of that narcotic substance. The sudorific properties of this compound are thought to render it eligible: although it has seldom any apparent effect, in that way, in diabetes. If the ipecacuan which it contains should disagree

with the stomach, an equivalent quantity of any other preparation of opium may be substituted for it.

There is another remedial measure which has also, in some cases at least, a most beneficial influence on the condition of the patient; I mean forced perspiration—perspiration induced by the hot air bath. Of this I have seen some striking examples. A very well-marked case of diabetes came under my care in the Middlesex Hospital several years ago. A vapour, or hot air bath, had just then been constructed in the hospital, and I thought it a good opportunity for trying whether the suspended functions of the skin might not be restored, and the extravagant action of the kidneys perhaps corrected, by that powerful mode of exciting perspiration. I should tell you that other plans of treatment had already been put in force, with but partial advantage. It would occupy more time than I can now spare to enter upon the details of this case; but I will read to you the man's own statement, which he wrote down before he left the hospital, in evidence of the benefit he derived from the *sudatorium*.

"The urine" (these are his words) "is reduced more than one-half, and does not contain much sweetness, but sometimes tastes salt, with a mixture of bitter. My stools, which were dry, and like balls packed together, are now quite natural. The pains in my limbs are entirely removed. My spirits, which were very much depressed, are now revived, and cheerful. The unpleasant aching of my kidneys, of which I spoke little lest I should be cupped in the loins, is now removed; only I feel weak there. I am cured of the pain in my stomach, and the circuitous working of the wind in my bowels, which formed lumps in my belly as it passed, resembling those formed by the cramp. I have likewise got rid of the palpitation at my breast, which was accompanied with a sort of dread. My breathing is much improved; perspiration, in a great measure, restored; and my skin, which was dry, is now become moist. I sleep well at night, whereas I *could* not sleep more than two or three hours out of the twenty-four. My thirst, which was excessive, has ceased to be troublesome."

This man, who, in the statement I have just read, has so graphically described his own morbid sensations, and the relief from them which he had obtained, left the hospital thinking himself well: *but*, the specific gravity of his urine remained above 1030.

In about half a year afterwards, he went one evening to Hyde Park to see some fireworks, got wet feet, and began to cough. The diabetic symptoms returned more severely than ever; and he soon died. I found his lungs stuffed with tubercles.

In furtherance of the principle upon which the use of the hot bath is recommended, the other well-known methods of promoting the natural functions of the skin should be followed; friction, and more especially warm clothing.

*Steel* is sometimes singularly beneficial in repairing the strength, and enlivening the spirits; as indeed it is well known to be in other forms of disease attended with a copious and permanent drain upon the system, and with a diminution of red blood. Of course it may be combined with opium, or with any other medicine which the circumstances of the patient may require.

I need scarcely say that the bowels need attention. Not that active purgation is advisable, but simply their regulation. Castor oil, rhubarb, aloes, lenitive electuary, are more appropriate in these cases than the purgative salts, which are apt to be diuretic also.

There is one other drug from which I think I have seen the happiest effects. I mean the *creasote*. I first became acquainted with its virtue, from prescribing it, almost accidentally, until a consultation could be arranged with Dr. Prout, for a child, eight years old, in whom the disease was well marked, and who had been brought to London from the country for advice. She had been rapidly wasting away for ten weeks, was extremely feeble, soon tired, very thirsty, especially at night, and had (what was also new to her) an enormous appetite. She was passing from three pints to two quarts daily of pale urine, having a specific gravity greater than 1040. I desired that her diet should be as exclusively animal as she could bear, and that she should take one minim of *creasote*, suspended by means of mucilage in an ounce and a half of water, three times a day. Curiously enough, the child liked the tarry flavour of the medicine. Upon this plan, with gentle aperients occasionally to regulate her bowels, she has remained for upwards of a twelve-month. Her urine soon fell in quantity within the limits of health, and in density to about 1030. She has regained her lost flesh, strength, complexion, and spirits, and grown considerably. If in any case a complete cure may be hoped for, I think it may in her, as she attains the period of womanhood. The brother of this little girl has lately manifested unequivocal signs of the same complaint; and in him it appears to have been equally checked by the same method of treatment.

There were two points in this young lady's case which deserve a passing remark. As her urine diminished in quantity it began to deposit the lithates. This Dr. Prout considered a very promising earnest of a return to a better diathesis: and I find that in cases which have crept on insidiously from the first, he is accustomed to *date* the malady from

the time when lateritious sediments, previously common, disappeared from the water.

The other point was, that calomel always sickened this child, and aggravated all the diabetic symptoms. This is consistent with Dr. Prout's experience, who tells us that he has never seen mercury do good in diabetic disease; but on the contrary almost invariably do mischief. I would advise you to read his judicious observations upon the too common abuse of that mineral.

I am quite aware of a possible fallacy in the case I have been mentioning, with respect to the efficacy of the *creasote*. With the use of that drug was associated a stricter adherence to a purely animal diet; and it is impossible to estimate with precision the separate effects of these two remedial measures. I am, however, disposed to believe that the *creasote*, by its well-known preservative property, checks the conversion of the food into sugar. And I think it is a mistake to go on increasing the dose. To most stomachs it proves irritating and hurtful when pushed beyond a certain small amount. Dr. M'Intyre tells me that he has found the *creasote* very useful in diabetes. I must however acknowledge that, in common with others, I have sometimes been totally disappointed by it.

For many years of my professional life I had not met with an instance of what has been called *diabetes insipidus*: from which I infer the rarity of that disorder. I shall use the term *chronic diuresis* to express this affection.

Very recently a marked instance of such chronic diuresis has presented itself in the hospital. A boy, eleven years old, not unhealthy looking, but lean, was admitted there under my care. He was much troubled by thirst; and by frequent micturition, which, even in the night, disturbed him many times. His bowels were costive, he had a capricious appetite, and his skin was dry. He voided during the twenty-four hours several pints, seldom less than nine or ten, of simply dilute urine, of a faintly yellowish hue, and having the specific gravity of 1002. Sometimes, indeed, it was found to be scarcely heavier than distilled water. In other respects he appeared tolerably well. It was supposed that he had been affected in this way for about twelve months; his desire for drink having been the first symptom noticed.

During his residence, of many weeks, in the hospital, under my observation, I made trial of every plan and drug that I could think of, for repressing the unnatural flux of urine. Nothing did him any good: some things, I fear, by disturbing his stomach and bowels, did him some temporary harm. He went out much as he came in.

Although I can tell you neither upon what this disorder depends, nor how it may be remedied, I mention the case because it afforded me a proof that liquid may be absorbed into the body from the atmosphere; either by the external skin, or by the pulmonary mucous membrane, or by both these surfaces. Dr. Prout, to whom I showed both the urine and the patient, advised that, for a time, his supply of drink should be limited. Accordingly, very much to the poor boy's sorrow, he was put upon a daily allowance of a pint and a half. I have no doubt that my injunctions were strictly observed, both by himself and by the nurses. Nevertheless, without losing flesh or weight, he passed, during the corresponding twenty-four hours, ten pints and a half of urine.

I got evidence of the same fact in another way also; namely by weighing the boy at short intervals: although the experiment was not repeated so often as I wish it had been. I give you the results of one of these trials.

Immediately after he had emptied his bladder he was found to weigh 3 st. 8 lb. 0 oz. 3 dr. Three hours subsequently, having taken nothing in the interim, he weighed 3 st. 9 lb. 0 oz. 2 dr. Then he voided 16 oz. of urine: after which his weight was again 3 st. 8 lb. 0 oz. 3 dr. So that he must have imbibed about a pound of liquid in that brief space of time.

In this instance there was merely an excess in the aqueous ingredient of the urine; the solid matters were apparently there, in their due proportion to each other, but in a very small ratio to the water.

But the aqueous ingredient may be in excess, while the absolute quantity of *urea* is deficient. On the other hand, with an excess of the watery material, there may be

an excess also in the quantity of *urea* it contains.

Dr. Willis has distinguished these three varieties of chronic diuresis by the terms *hydruria*, *anazoturia*, and *azoturia*, respectively. Although I am no friend to the multiplication of technical names, I must tell you that the distinctions expressed by these terms are real, and of some importance. Anazoturia we shall find to be often symptomatic of a peculiar organic disease of the kidney, which I hope to describe in the next lecture.

Azoturia, which is accompanied by an unnaturally high specific gravity of the urine, is apt, on that account chiefly, to be mistaken for diabetes. As recoveries from it are not uncommon, it may be suspected that some of the boasted cures of diabetes were cures of this less serious disorder. In the one case, the yeast test detects the presence of sugar in the superabundant urine; in the other case it finds none.

CONTRIBUTIONS  
TO THE  
CHEMICAL PATHOLOGY OF SOME  
FORMS OF MORBID DIGESTION.

BY GOLDING BIRD, M.D., A.M., F.L.S.  
Member of the Royal College of Physicians,  
Physician to the Islington Dispensary, and  
Lecturer on Medical Physics at Guy's Hospital.

(Continued from p. 397.)

IN the following table we have, at one view, the proportion of hydrochloric and of organic acids present in the vomited fluids from the patient whose case has been narrated.

Quantity of vomited fluid.	Date when vomited.	Quantity of real hydrochloric acid.		Quantity of free hydrochloric acid of the strength of the fluid acid of the pharmacopœia.	Quantity of potass required to neutralize the organic acids (acetic, lactic, butyric).
		Free.	Combined.		
3xx.	Oct. 28, 1840	10·652 gr.	15·228 gr.	32·9 gr.	3·0 gr.
3xx.	Nov. 12, 1840	7·108 gr.	18·272 gr.	22·0 gr.	6·7 gr.
3xx.	Nov. 17, 1840	1· gr.	22·320 gr.	3·09 gr.	16·9 gr.

From the chemical pathology of this case of scirrhus pylorus we may draw the following inductions:—

1. That the gastric secretions are persistently acid.
2. That they are always more or less coloured, and contain, in suspension, sebaceous particles.
3. That free hydrochloric exists, in considerable quantity, in the vomited fluids during the more irritative stage

of the disease, and gradually disappears as the powers of life sink.

4. That free organic acids are secreted, and are met with abundantly, in the vomited fluid; at first co-existing with the hydrochloric acid, and subsequently nearly replacing it. These acids are most probably lactic, acetic, and butyric.

These inductions are certainly interesting, and, if corroborated by the

examinations of other cases, cannot but be of some importance. Certainly they are supported by a less minute investigation I made in two other cases; but the extremely tedious nature of investigations of this kind proves an important barrier to their being multiplied by one observer.

Not only are these observations borne out by the phenomena presented by disease when actually involving the pylorus, but, so far as my own observations extend, equally apply to cases in which great pressure is excited on that portion of the stomach by organic mischief in a neighbouring organ. I shall content myself with citing a single case in support of this statement. I give it in the words of Mr. Walker, of St. John Street, in whose practice it occurred.

**CASE XIX. — Malignant Tubera of Liver pressing upon the Pylorus — Icterus — Death.**

"Mrs. L. æt. 30, fourteen months ago complained of violent pains in the regions of the stomach and liver, darting through to the back between the scapulæ. Vomitings of a bilious character soon made their appearance, and increased to that degree that only two dinner-meals have been retained in the stomach up to the present period, Aug. 23, 1841. There is little doubt but her illness has been partially produced by over anxiety in business, and other circumstances; denying food for some time, and passing sleepless nights. She has suffered through life from obstinate constipation, going a whole week without an evacuation. She has two children, the youngest of which is subject to constipation, but is, in other respects, healthy. Mrs. L.'s appearance, at the present time, is emaciated, and denotes considerable suffering, the pains over the stomach having been violent and throbbing, and only to be alleviated by opium, which, for some time past, has been administered. Aphthæ have made their appearance on the tongue, lips, and gums. She also complains of great thirst. This day, the 23d, she was seen by Dr. Golding Bird, when his attention was directed to the stomach and liver; and after examination of the contents of the stomach, and the region of the liver, he discovered some irregularities, with defined and hardened edges, and pro-

nounced the disease to be tubera of the liver, with, probably, scirrhus enlargement of the pyloric orifice of the stomach. A quantity of the brown fluid vomited was examined; it reddened litmus paper; and on filtering the same, and touching it with argent. nit. produced a flocculent precipitate, which was taken up on the addition of liq. ammonia. The urine was small in quantity, and of a yellowish-brown colour; fæces clay-coloured, and offensive. Dr. Bird ordered some aperient pills to keep up the action of the bowels; but they were rejected, when she took the Rose Mixture, with Epsom Salts, which partially acted. In the evening, complaining of feebleness in the bowels, I gave her Ol. Croton. gt. i. and repeated it in two hours, when she had rather a copious evacuation, retaining on the surface impressions of the small intestines.

25th.—Had a discharge of blood from the vagina, and, on examination, found os uteri dilated; and two hours after an embryo was expelled. None of the symptoms of pregnancy had been presented, owing, as I suppose, to being masked by the disease.

26th.—Vomitings of the same character, but not so violent; and she appears altogether more tranquil.

28th.—Vomitings considerable; and almost every thing she takes is rejected, with the exception of a little sherry and water.

29th.—Icterus appeared; complains of drowsiness, and pain in the head; rejects her medicine. Dr. Bird saw her, and ordered—

Argent. Nit. in gr.  $\frac{1}{4}$  doses ter die.

31st.—Vomitings worse, and producing great exhaustion; the only thing retained, and that only for a short period, is soda water and brandy, which she drinks in large quantities. Her tongue is now covered with aphthæ. Injections of beef-tea, and yolk of egg, were ordered by Dr. Bird.

Sept. 2d and 3d.—Gradually getting worse.

4th.—Dr. Golding Bird ordered the effervescing draughts, with ammonia; but they were rejected: in fact, any thing, as soon as it reaches the stomach, is immediately cast up.

5th.—Restless, with continued faintings throughout the day, with a quick fluttering pulse.

She died at a quarter past six o'clock the next morning."

*Post-mortem examination, 10 hours after death.*—*Head*: not examined. *Chest*: healthy. *Abdomen*: the irregularities felt during life on the surface of the liver were found to be made up of two large orange-coloured tubera, each the size of an egg, and projecting above the convex surface of the organ. The fundus of the gall-bladder projected considerably. The viscus itself was distended with black bile, holding in suspension a carbonaceous powder. One large tube pressed on the pyloric end of the stomach, and so interfered with the contents of Glisson's capsule as to prevent food passing through the former, and bile finding its way through the ducts. On cutting into the liver, the bile-ducts were everywhere distended, and great venous congestion existed. Stomach much distended: its pyloric extremity thickened, and so pressed upon by the tubera as nearly to obstruct the passage of a fluid through it. The ovaria contained some irregular yellow granular bodies, resembling those found in the liver.

*Examination of the fluid vomited on August 23, 1841.*—The vomited fluid exceeded a quart in bulk. It was of the consistence of gruel, and possessed a faintly acid odour. When strained through a cloth, a grey clay-like pul-taceous mass was separated from the pale-brown fluid portion. The latter passed through a paper filter with readiness, and then presented the colour of pale ale.

1. An ounce of the filtered fluid was distilled until five drachms had passed over; the remainder, evaporated to dryness, left a very acid brown extract.

2. By repose, a semi-crystalline fatty pellicle concreted on the surface of the distilled fluid, closely resembling that formed in the specimens obtained from the last case.

4. The distilled fluid actively red-dened deep-blue litmus paper, and did not become opaque on the addition of nitrate of silver. The f3v. required four minims of liquor potassæ for saturation. Evaporated to dryness, after

being thus saturated, a crystalline yellowish residue was left, which, on the addition of a drop of sulphuric acid, effervesced violently, and evolved a penetrating odour of acetic and butyric acids.

5. An ounce of the fresh vomited fluid required thirty-two minims of liquor potassæ for saturation.

6. An ounce of the fluid, evaporated and incinerated, precipitated from nitrate of silver four grains of chloride; and after neutralization with potass (A. 7, B. 4), the same quantity yielded 4·48 grains.

From these experiments it appears that each pint (3xx.) of the vomited fluid required rather more than 3xss. of liquor potassæ, equal to about thirty-six grains of the free alkali, for the saturation of the uncombined acid; and of this enough was volatilized, at a low temperature (1), to neutralize rather more than a drachm of the alkaline solution.

The quantity of free and combined hydrochloric acid, being calculated from the quantity of chloride of silver (6) precipitated by a solution of the ash obtained from each ounce of fluid before and after neutralization, we find that in each pint of 3xx. there existed—

Free and combined hydrochloric acid	22·61 gr.
Combined hydrochloric acid	20·30 gr.
<hr/>	
Leaving, of the free acid, only	2·31 gr.
equal to very nearly 7·5 grains of the fluid acid of the shops.	

As the quantity of hydrochloric acid in 3xx. of vomited fluid (2·31 grs.) was only sufficient to neutralize 3 grains of potass, it follows that enough of some acid, destructible by heat, to saturate 33 grs. of the alkali, must have been present. This acid, in all probability, consisted of acetic, lactic, and butyric. We have positive evidence of the first and last existing in the distilled fluid; and the second we know to be a tolerably constant ingredient in animal secretions generally.

The following table shews the relative proportions of free and combined acid at one view:—

Quantity of vomited fluid.	Date when vomited.	Quantity of real hydrochloric acid.		Quantity of free hydrochloric acid in grs. of acid of the shops.	Quantity of potass required to neutralize the organic acids.
		Free.	Combined.		
3xx.	Aug. 23, 1841.	2·31 grs.	20·30 grs.	7·5 grs.	33 grs.

In this case, as well as in that of scirrhus deposit in the pylorus itself, we find an enormous quantity of an organic acid secreted. It certainly would appear that *pari passu* with the extension of the disease, the hydrochloric acid disappears, and the organic acids increase.

To obtain satisfactory information regarding the positive increase of the organic acids in disease, we must have some data derived from the examination of healthy secretions wherewith to compare them. This must probably for some time be a desideratum. The only approach to definite information I can give on this head is derived from

an examination of the fluid matters vomited during digestion after the exhibition of an emetic of sulphate of zinc. The person was a young man under my care, at the Finsbury Dispensary, for a trifling rheumatic ailment, being otherwise in perfect health. He took ℞j. Zinci Sulphas half an hour after a tolerably hearty dinner; and the vomited mass was thrown on a flannel strainer: a scarcely-coloured acid fluid passed through, and the following is the result of my examination, which, however, from being made on a single case, can scarcely be regarded as even approaching to satisfactory information:—

Quantity of vomited fluid.	Date when vomited.	Quantity of real hydrochloric acid.		Quantity of free acid of the strength of the pharmaceutic preparation.	Quantity of potass required to neutralize the organic acids.
		Free.	Combined.		
3xx.	Nov. 17, 1840.	3.45 grs.	5.07 grs.	12. grs.	2.43 grs.

In this case we find the ratio of hydrochloric to organic acids to be as 1 to 1.4; whilst, in the preceding one, it was ten times more, or as 1 to 14—a disproportion so enormous, that, making all allowance for errors of observation, we can scarcely help referring it to the effect of diseased action.

I only regret, in thus bringing to a close the remarks I have taken the opportunity of making on the chemical characters of vomited fluids in some

gastric affections, that the amount of information I have to offer has been so scanty. For this the very tedious and laborious character of investigations of this kind must plead an apology; and I trust this important subject will be further elucidated by those who have more time to devote to the task than falls to my lot.

## ON ARTIFICIAL CLIMATES.

By JULIUS JEFFREYS, F.R.S., &c.

[Continued from p. 222.]

### ON THE ATMOSPHERIC TREATMENT OF CHRONIC DISEASES OF THE CHEST.

#### *On the Respirator.*

THE above is an explanation, sufficiently full, of that portion of the physical principle of the Respirator which relates to its power of transferring heat in the most advantageous manner between currents of air which are passing it, not simultaneously but alternately, and in opposite directions. It has been shown that a peculiar construction is requisite for effecting this, consisting of a number of distinct depositories of warmth of different

grades of temperature, progressing from the outermost, which is nearly at the temperature of the air, to the innermost, which may be given nearly the temperature of the breath. It will have been seen, then, that in order to command the full action of the principle, not only is the quickly conducting power of metal necessary, and an extreme subdivision of it and of the air subjected to its influence, but a system also, or series of depositories of heat, without which the effect would be very inferior.

It will here be proper to notice the different action of the Respirator, in its conducting capacity, from one or two articles with which it is often confounded.

From want of attention, persons abundantly qualified to discern between the two have often spoken of it as a

modification only of the action of the woollen wrapper commonly worn over the mouth, and named a comforter. A little attention will suffice to render it manifest that the woollen wrapper and the Respirator not only do not act upon the same principle, but that they are at opposite extremes in their action.

To act most perfectly for keeping off cold from the surface of the body, a substance should be a most perfect non-conductor of heat. That wool is such we can little doubt, when we consider that unlimited knowledge, skill, and power, have clothed the sheep with its fleece. Hence, upon trial, we find that the fibre of wool has the least possible power of transferring warmth. And in the case of a fleece, or of clothing, the interstices unoccupied by the fibre detain in them air, which, when thus fixed, is equally slow to transfer heat. Such a material on the body is admirably qualified to keep in the animal warmth. In the use of wool for clothing man was following an example which would guard him from the possibility of error; but when he employs the materials of nature unguided by a Divine example, much caution and study of the laws of their action are requisite to preserve him from a confused misapplication of them. Thus the endeavour to protect the lungs by wrapping over the mouth that which gave comfort to the body, though an inviting measure, was an entire desertion of the Great Example, and altogether erroneous.

In the case of the lungs, the warmth to be preserved is not travelling off by itself, but is combined with the impure breath, which ought all to be freely voided. If we breathe over woollen fibre, this substance, true to the property implanted in it, will not conduct or transfer any appreciable quantity of warmth from our breath; and when we next inhale cold air, the wool will have no warmth to give it; and if it had, it would give none, being a non-conductor. Hence, if we breathe backwards and forwards over wool, at every out-breathing all the warmth will be lost, and at every in-breathing cold untempered air will enter the throat, in the same manner as when the face is uncovered. To produce any effect, it is necessary to make the woollen wrapper very bulky and spongy. Though it still fails to conduct any heat, its

bulk enables it to detain a considerable quantity of the breath itself, especially as the breath can spread to the right and left over the cheeks in breathing out. At the next breathing in, this body of warm impure air is mixed up with the cold pure air, and tempers it in a trifling degree; but then this is at the expense of its purity. Hence the oppression felt, and the unwholesome action of any wrappers which are so bulky as to produce any warming effect on the breath; and even with this unwholesome contingency, the effect is too trifling to be relied on by the pulmonary invalid.

The property of non-conduction with which wool is endowed by Infinite Wisdom, which never intended it for a Respirator, may assure us that the action of the woollen wrapper is no other than the above, small as that warming action is. Nearly the same may be said of all fibrous matter of animal or vegetable origin. Non-conduction is their characteristic, while the Respirator requires the most perfect conducting power attainable in its materials, aided by the peculiar construction described.

Another remark not unfrequently made is, that the Respirator acts upon the principle of the safety-lamp of Sir Humphry Davy. This is by no means correct. Their only points of resemblance are two. One they have in common with a kettle, or boiler, or any other instance of conduction through the medium of metal. The other point of resemblance is, that in both the conduction is of the nature which may be named *interstitial*. The fluid and the metal are, as it were, mixed up together, the particles throughout the interstices of the one acting upon those of the other; for effecting which the metal is given the form of fine wire. But the resemblance goes no farther. In the safety-lamp, the conduction is continuous, as in an instance formerly noticed, or as in the case of a boiler. The upper portion of the gauze conducts heat without intermission from the hot air going out: it is a case of uninterrupted continuous conduction, and wire, in that case, is only a roadway for the heat, not a storehouse of it. And as the heat of the inflamed gas in the lamp is far higher than that of the outer air, comparatively coarse means suffice to extinguish the flame.

But in the respirator, the conduction, as has been explained, requires to be of the depositive or storehouse kind. In this respect it rather corresponds with the heater of an urn, or the iron used in soldering; which are depositories of heat received in a fire, and afterwards yielded to other matter as we may wish. With respect to the gradative character of the conduction of the Respirator, I do not know of any other instance in which it is employed. This provision, embodied in the finest workmanship, is necessary for recovering the comparatively small warmth of the breath, and transferring it to a medium so much nearer in temperature to it than in the case of the safety lamp. Hence I found the ordinary resources of the finest manufactures in metal of much too coarse a nature to give the perfect effect I desired to a philosophical principle which was of so delicate a nature as to be in danger of slipping, as it were, through the fingers.

Warming the air inhaled is not the only action performed by the instrument. Were it so, it would have been very imperfect. It may be well understood, from all the foregoing remarks, that I should have felt averse to raising air, already dry perhaps at the freezing point, up to 70° in an instant, without any provision for moistening it. While reflecting upon the subject, it became evident, that a deposition of moisture condensed on the outgoing breath ought to be found on the wires; and, on trial, the gaining of so important a point proved very encouraging; for it was also obvious that this moisture would be, in part at least, dissolved by the entering current, which would thus be given humidity as well as warmth; the two actions falling together in happy accordance. The cases which have come before my notice, in which the presence of this humidity has been of the greatest benefit, have been so numerous, and its action so manifest, as, by the irresistible power of fact, to negative any counter-hypothesis which, grounded upon some partial view or loose analogy, might be raised against offering moisture with warmth continually to the membrane while in an irritable state. There can be no question, as has been noticed already, almost too often, in the preceding

pages, that keeping *the whole body* in a similar atmosphere would be as improper as it would be a practice altogether different from the other in its principle and action.

On this last consideration rests the seventh indication enumerated in my last paper—that of favouring the action of the skin by not overloading it with clothing: for when the pulmonary membrane is thus allowed to diminish the quantity of the exhalation which it can ill supply while irritable, it may, in many cases, be well to favour a vicarious action by the skin; and it is undeniably desirable to maintain active circulation in the surface. Now we find, as a part of the physiological action of the Respirator, that it must, from its principle, possess, in a powerful degree, the property of diffusing warmth over the whole system. The quantity of heat lost by the lungs in respiration, partly in raising a cold air up to the blood heat, and in part in the form of latent heat carried off in the vapour exhaled, repeated as the act is so quickly and constantly, is doubtless very large. I shall not here occupy time by relating attempts to estimate it; but the amount is such as abundantly to account for the chilly state of the body generally, where the lungs are diseased or enfeebled. Now the quantity of the warmth thus carried off is so much less, when the Respirator is worn, that the effect is not felt in the chest alone, but gradually, in a greater or less degree, over the whole body. That this collateral result would flow from the principle was too manifest to escape observation, and it was therefore noticed in the little essay I printed before it became established by trial. Very soon afterwards I met with persons describing of their own accord this general warming effect as a source of comfort; and what is curious, several remarked that it answered the purpose of a great coat; thus in very terms showing its fulfilment of the seventh indication. In my own person, when suffering from a bronchial affection, I have experienced this at times, when, without the instrument, not only was distress felt in the chest, but the limbs could not be kept warm out of doors. I am now acquainted with many similar and more striking cases. In that of one medical gentleman the instrument is worn more on account of this power

of diffusing warmth over the body, than for any immediate need of protection by the lungs.

Omitting all minor points, there remain to be offered a few observations upon the investive parts of the instrument. These, for the purpose of guarding the metallic storehouse from a dissipation of the warmth, ought to be of material very slow to conduct heat. Soft leather, on this account, and from its being the most flexible and pleasant material to apply to the face, was selected; and I have not had any reason, from experience, to direct the employment of any other. To one point more especially I would call the attention both of wearers and of those who recommend the use of the Respirator; namely, the keeping the leathern folds, or tucks, which apply themselves to the lips, in a sufficiently elevated state, by means of drawing-strings with which they are provided, to prevent the lips from pressing against the metal-work. When this takes place, the area of the instrument which can supply the draught equals only the orifice of the mouth; for the lips form a kind of valve round the surface they touch. On an average of mouths three quarters of the surface would be thus excluded from acting. Hence in these cases, which are of frequent occurrence, the freedom with which the air is drawn, as well as the

warming effect, is materially lessened. It may be interesting to the professional reader to consider the arrangement for making the area of the surface of the instrument bear a determined relation to the area of the orifice of the human glottis, in its usual partially open state, or of the narrowest part of the trachea. I have taken the value of this area, or free-way of the air-passage in the human male adult, at twenty-four square sixteenths of an inch, or equal to a parallelogram half an inch long by three-sixteenths wide (A A A, &c.) This is perhaps equal to the largest tracheæ. An orifice of that size, if not lengthened out into a tube, would therefore supply air freely to the lungs, as in the case of the contracted portion of unobstructed nostrils. Now, I suppose, in the case of the Respirator, the multitudinous subdivision of the air current by the wire-works may increase the resistance to the motion of the currents twenty times, requiring twenty of such parallelograms to supply the windwipe readily. But as the wires themselves take up one-third of the whole surface, thirty have to be allowed. In order to render the passage abundantly free, I increased the number one-third more, or to forty, to which, to preserve the rectangular form, I added two, making in all forty-two of these parallelograms or compartments, in the man's Respirator. For fe-

males I have reduced the area about one-fourth, and have given them thirty compartments; and to children (supposed under twelve years of age) twenty compartments. Experience seems to justify these provisions, where attention is paid to the point above insisted on—that of keeping the lips off the metal work; but I would be happy to attend to the suggestions or corrections of my esti-

mate by any more able anatomist and pneumatician.

The complete Respirator, then, is an instrument consisting of a series of highly conducting depositories of warmth, invested by non-conducting parietes of leather, passing next the face into soft cushions, which apply themselves closely to the lips and cheeks. I do not here occupy the reader with

the minor details of the arrangements for rendering the same instrument, by flexibility and other provisions, adaptable to all varieties of feature.

*On the Protective and Restorative Effects of the Respirator.*

The limit I have set to the space occupied by the various subjects discussed in these papers, renders the present account necessarily imperfect, I do not, therefore, here undertake, in considering its medical action, to speak of the various affections of the respiratory organs separately, in which the Respirator has been, or may be employed with benefit, but I shall confine my remaining remarks to a general statement of facts of experience. The preceding matter, which has consisted chiefly of arguments and views rested upon principles in physiology and medicine, however stable in theory, would fail of obtaining the assent of many persons, unless it could be shown that sufficient *trial* had established its truth. Nor would a few cases suffice; for it is to be regretted that where the speculator is himself the observer, in medical cases which put his views to a trial, a bias in favour of the offspring of his own mind is liable to mislead him, and to cause a person, not by any means indifferent to the high demands of truth, to find cases suitable to his views. We have instances of opposite hypotheses, thus supported, at the same moment by medical cases.

As objections have been raised to the principle of the Respirator, and to the medical views upon which its use is rested, and as even to this day, and within the profession, grave, but far-fetched arguments are to be heard against it (some having to go to the tropics and the polar regions for them), instead of troubling the reader by pointing to the loose foundation on which they are rested, I shall state a summary of facts, not of my own experience only, but also of many hundreds related to me by professional and other observers, upon an experience of five years, in this and other countries. Upon the grounds I am in possession of, I consider the number of regular wearers, in this country, of the Respirator in the winter to range at present between fifteen and twenty thousand. Though this number, owing to the great prevalence of disorders of the organs

of respiration, may not exceed one-fiftieth of all the cases of a nature to be benefited by its use, it is large enough to afford an ample field of experience.

My opportunities of observing the effects of the Respirator, though not equal in extent to what, by a more frequent contact with the public, might have been commanded, have nevertheless been considerable.

Were the benefit in each individual case of small extent, when multiplied into so many thousands, the collective amount of its utility to the public would be still considerable. Its effects, however, have extended far beyond this. Did their amount confer merit upon the inventor, I should prefer leaving to some other person the duty of detailing them as evidence. But I do not claim merit on this ground. Had there been only one, instead of a million cases to which it was suitable, the line of thought ending in the physical portion of the invention, and any aptitude for construction giving rise to the mechanical part of it, would have been just the same, though, in that case, the resulting instrument would have been useless to all but that one individual. The following, then, is a summary of the effects, collected partly from my own observation, but chiefly from that of others, during a period of five years:—

After having invited communications from wearers of the Respirator at all times, I find the proportion of cases of disappointment to be very small, and chiefly confined to two kinds; first, where, as before noticed, the lips are brought in contact with the metal, thus diminishing the free-way of the instrument, and, to some extent, the freedom of respiration; and, secondly, where Respirators of more warming power than was suited to the feelings of the wearers, or the temperature of the weather, had been employed. It is obvious that a power suited to a cold winter day must be too great for spring weather; for which the Respirator of lowest power is provided.

With these and a few other exceptions, I may almost affirm that the instrument has been universally beneficial, though, in the numerous cases, in which other than atmospheric causes are the chief sources of distress, the benefit is necessarily limited: yet any benefit, obtained without the least in-

jury or uneasiness to counter-balance it, is a gain of which no considerate person will be insensible.

In its second degree of benefit, it has lessened the severity of cough by day, as well as by night, where it has not secured complete rest.

In its next, by their enjoyment of air, exercise, freedom of respiration, and of the circulation through the flow of warmth to the extremities, and by the consequent improvement of their spirits, it has qualified persons for the performance of duties they had long been compelled to lay aside. When it is productive of this degree of benefit, we are brought amongst cases of much interest in the history of its action. In many, to these advantages by day, it has added the important effect of giving complete rest at night. Persons who were strangers to any period of unbroken sleep, enjoy a whole night's rest of the most perfect kind.

I have seen a person bent down with asthmatic distress, emaciated, and weak in body, and in mind dejected by suffering, and by the cares of a family, whom every year he was becoming less able to provide for, by the aid of the Respirator alone brought to the following state:—His attitude has become more erect; he has acquired more flesh than he had had for many years; his ease, at night, as well as by day, has been such as he never hoped to enjoy; his time has been quite restored to his family; and his anxieties have been all removed.

No cases are more striking than of those asthmatics, whose local symptoms depend much on the temperament of the atmosphere, especially of those who do not presume upon the first relief they get, and relax from the caution in diet which they had before been compelled to exercise.

Others there are, who had to incur serious injury to their affairs, and painful separation from their families for several successive winters, by leaving England, who, under the protection of the Respirator, have remained for some years in the bosom of their families. I know of cases of this kind where the improvement of health has been so considerable, that the parties are now actively engaged in business. I am acquainted with the cases of medical men, some in large practice, who have resumed labours valuable to the com-
